2Department of Earth and Planetary Sciences, University of New Mexico, Albuquerque, New Mexico, 87131

Abstract—Triassic strata crop out around the Sandia uplift in the Hagan basin, Placitas and Cedar Crest areas. A uniform Triassic section of nonmarine red siliciclastics as much as 480 m thick is exposed across all three areas. The base of the Triassic section is the Middle Triassic (Anisian) Anton Chico Member of the Moenkopi Formation, which disconformably overlies Permian limestones of the San Andres Formation. Moenkopi strata are as much as 20 m thick and mostly grayish red/pale-red litharenitic sandstones and siltstones. They are disconformably overlain by the Agua Zarca Formation of the Chinle Group, as much as 108 m of mostly yellowish gray sublitharenitic sandstone and extraformational conglomerate with clasts of quartzite and Paleozoic limestone. Overlying gray and purple mudstone dominated strata, as much as 92 m thick, may belong to the Salitrail Formation. The uppermost Triassic strata exposed around the Sandia uplift are as much as 260 m of mostly reddish brown bentonitic mudstone assigned to the Petrified Forest Formation. A prominent, bench-forming sandstone/conglomerate unit as much as 37 m thick at the top of the Petrified Forest Formation is the Correlo Member. It is disconformably overlain by the Middle Jurassic Entrada Sandstone. Few paleontological data are available from Triassic rocks around the Sandia uplift, but they can be readily correlated to nearby Triassic strata on the southern Colorado Plateau and on the southern High Plains, principally by lithostratigraphy.

INTRODUCTION

Triassic strata exposed around the Sandia uplift in Bernalillo and Sandoval counties, New Mexico, crop out in three areas (Fig. 1). The largest Triassic outcrop belt is in the Hagan basin, an eastward tilted half graben that forms an embayment on the northeastern side of the Albuquerque basin. Immediately to the south, Triassic strata crop out around Placitas in a structurally complex transition and accommodation zone between two en-echelon, rift-bounding faults. To the southeast, on the eastern dip slope of the Sandia uplift, Triassic strata are exposed around Cedar Crest.

Our purpose here is to review the stratigraphy of these Triassic outcrops to demonstrate that they present a nearly uniform Triassic section around the Sandia uplift. We also correlate these Triassic strata with those elsewhere in New Mexico. In this article, NMMNH refers to the New Mexico Museum of Natural History and Science, Albuquerque.

PREVIOUS STUDIES

Very little has been published on the Triassic strata surrounding the Sandia uplift. However, extensive data have been presented in University of New Mexico master's theses completed by Harrison (1949), Reynolds (1954), Picka (1982) and Menne (1989) (Fig. 2). Principal published works are Stearns (1953), Smith (1961), Kelley and Northrop (1975) and Lucas (1991) (Fig. 2).

Harrison (1949, p. 70-80) assigned Triassic strata in the Hagan basin to the Dockum Group with a total thickness of 2101 ft. Although he attempted no further subdivision of the Triassic section, Harrison (1949, p. 78) identified a "bottom 330 feet sandstone unit" overlain by red-bed mudstones.

Reynolds (1954, p. 22-24) identified this sandstone-dominated interval as the Santa Rosa Sandstone overlain by red-bed mudstones of the Chinle Formation. He included both the Santa Rosa and Chinle in the Dockum Group, and reported a Santa Rosa thickness of 335 ft and a Chinle thickness (p. 24) of 1790 ft.

Stearns (1953, p. 465, fig. 2) merely assigned Triassic strata in the Hagan basin and Placitas area to the Dockum Group. He described these strata as 800 feet of "red and variegated sandstone and shale."

Smith (1961, table 1) assigned Triassic strata around the Sandia uplift to the Dockum Group, divided into a basal Santa Rosa Sandstone overlain by an "upper member." He described (p. 123) Harrison's (1949) report of a total Triassic thickness in the Hagan basin of 2100 feet as "excessive."

Kelley and Northrop (1975, p. 52-53, fig. 10, map 1) divided the Triassic section around the Sandia uplift into the Santa Rosa Sandstone overlain by the Chinle Formation and included both units in the Dockum Group. They estimated the thickness of the sandstone-dominated Santa Rosa Sandstone as about 100-400 ft, and the red mudstone dominated Chinle Formation as about 1300-1400 ft. Kelley (1977) repeated these observations (also see Kelley, 1965). Kelley and Northrop (1975, p. 52) also identified as Permian "Bernal Formation" as much as 75 feet of "tarn-brown" sandstone between their Santa Rosa Sandstone and the underlying Bonney Canyon Member of the San Andres Formation.
Chinle Formation as a "laterally-persistent Correo-equivalent." Moenkopi Formation (Lucas and Hayden, 1991). Overlying Triassic strata are disconformably overlain by as much as 13.5 m of red-bed micaceous siltstone and conglomerate; Santa Rosa Formation of Wood and Northrop (1946). We reject previous use of the term Santa Rosa Formation for these strata because the uppermost, sandstone- and conglomerate-dominated interval of the Petrif­ied Forest Formation is identified as the Correo Member (Lucas et al., 1987, 1988; Lucas, 1991, 1993; Lucas and Heckert, 1994). The follow­ing text describes these units in detail and correlates them to nearby Triassic sections.

HAGAN BASIN

Around the Sandia uplift, Triassic strata are best exposed in the Hagan basin and were well mapped there most recently by Kelley and Northrop (1975, map 1) and Picha (1982, Fig. 1). Lucas (1991) described these strata in some detail and illustrated selected outcrops and fossils. We present here the data upon which Lucas (1991) based his description — five measured sections (Appendix 1, sections A-E) — and present a more detailed description. The basal unit of the Triassic section in the Hagan basin is the Anton Chico Member of the Moenkopi Formation. Our section A, at which the Moenkopi Formation is 20 m thick, is representative (Fig. 3). Here, the Moenkopi disconformably overlies limestone of the Permian (Guadalupian) San Andres Formation and is disconformably overlain by conglomerate of the Agua Zarca Formation of the Chinle Group. Most of the Moenkopi Formation is pale red and very pale orange litharenitic sandstone that is trough crossbedded and ripple laminated. A subordinate rock-type is pale red siltstone.

The base of the overlying Agua Zarca Formation is typically a clast-supported, trough-crossbedded conglomerate. Clasts are extraformational quartzite, Paleozoic limestone and Moenkopi limestones. Fossil logs are com-

FIGURE 2. Comparison of stratigraphic nomenclature applied by previous workers to Triassic strata around the Sandia uplift with that advocated in this paper.

FIGURE 3. Stratigraphic sections of the Moenkopi Formation around the Sandia uplift. See Appendix for lithologic descriptions and locations of sections.
mon locally. Overlying Agua Zarca strata are mostly gray and yellowish gray trough-crossbedded, laminated, and ripple-laminated sublitharenitic sandstones. They typically form a prominent hogback. We measured Agua Zarca Formation thicknesses in the Hagan basin of 108.4 m (section B) and 87.1 m (section C) (Fig. 4).

The remainder of the Chinle Group in the Hagan basin is a thick, red mudstone-dominated unit that forms a long, N-S strike valley between the San Andres-Agua Zarca hogback to the west and the Jurassic Entrada hogbacks along Cañon Tejon to the east (Kelley and Northrop, 1975, map 1: Picha, 1982, fig. 1). In our section B (Fig. 4), the lower 91.6 m of this mudstone-dominated interval (units 11-21) are mostly gray and purple bentonitic mudstones and intraformational conglomerates that resemble, in stratigraphic position and lithology, the Salitral Formation of the Chama basin-Nacimiento uplift to the west. Lucas, (1991, p. 49) also noted this similarity, and we tentatively assign these strata in the Hagan basin to the Salitral Formation, even though the Poleo Formation, which overlies the Salitral Formation in the Chama basin-Nacimiento uplift, is absent in the Hagan basin.

Chinle strata above the Salitral Formation in the Hagan basin are 260.7 m (our section B: Fig. 4) of mostly grayish red and reddish brown bentonitic mudstone with relatively thin beds of litharenitic sandstone and intraformational (calcrete-clast) conglomerate. We assign these strata to the Petrified Forest Formation, as that unit was redefined by Lucas (1991, 1993) and Lucas and Hunt (1992).

The uppermost strata of the Petrified Forest Formation in the Hagan basin are a prominent ledge of crossbedded litharenite and mostly intraformational (some extraformational quartzite clasts are present) conglomerate. Following Picha (1982), Lucas et al. (1987, 1988) and Lucas (1991, 1993) we correlate this unit to the Correo Member of the Petrified Forest Formation in the Lucero uplift to the west (see Lucas and Eckert, 1994). We measured thicknesses of the Correo Member in the Hagan basin of 37.3 m (section B), 21.8 m (section D) and 5.4 m (section E) (Fig. 4). These thickness variations probably reflect differential erosion associated with the J-2 unconformity surface (Pipringos and O'Sullivan, 1978) between the Correo and the overlying medial silty member of the Middle Jurassic Entrada Sandstone. Indeed, in the Hagan basin, the Entrada appears to bevel off the Correo completely at Puertecito in the SE1/4 SW1/4 SW1/4 sec. 10, T12N, R5E. Throughout the Hagan basin, the medial silty member of the Entrada rests disconformably on the Correo Member of the Petrified Forest Formation or on a thin (<5 m) interval of red mudstone of the Petrified Forest Formation just above the Correo Member.

**PLACITAS AREA**

Triassic strata crop out along the northwestern edge of the Sandia uplift southwest of the village of Placitas in the NE corner of T12N, R4E and the NW corner of T12N, R5E. Kelley and Northrop (1975) and Menne (1989, Fig. 1-2) mapped the distribution of the structurally complex Triassic outcrops in this area. Menne (1989, p. 130-134) also described three stratigraphic sections of Triassic rocks in the Placitas area, and our sections and observations (Appendix 1, sections F-H) are in close agreement with hers.

The base of the Triassic section in the Placitas area is the Anton Chico Member of the Moenkopi Formation which disconformably overlies limestones of the Permian (Guadalupian) San Andres Formation. The Moenkopi Formation is grayish red and reddish brown micaceous litharenitic sandstone and mudstone as much as 13.5 m thick. Its best exposures are at our section G (Fig. 3), near the head of the dirt road in the NW1/4 SE1/4 NW1/4 sec. 7 (unsurveyed), T12N, R5E and just northwest of Tunnel Spring in the NW1/4 SE1/4 SW1/4 sec. 5, T12N, R5E.

The Agua Zarca Formation of the Chinle Group disconformably overlies the Moenkopi Formation in the Placitas area. Menne (1989) estimated its total thickness as about 67 m. It is mostly grayish yellow to greenish yellow quartzarenite sandstone that is not very well exposed (Fig. 4).

Overlying red mudstones of the Chinle Group are at least 169 m thick but their base and lower one third to one half (?) are nowhere well exposed in the Placitas area (Fig. 4). The best exposures of these red beds,
which we correlate to similar Petrified Forest Formation strata in the Hagan basin immediately to the north, are in the SE1/4 NE1/4 sec. 1, T12N, R4E, just south of NM highway 44. Here, the upper portion of the Petrified Forest Formation is dominated by reddish brown bentonitic mudstones with thin ledges of litharenitic sandstone and intraformational conglomerate. The uppermost 15-20 m of the Petrified Forest Formation forms a prominent ledge of conglomerate and sandstone we identify as the Correo Member. Menne (1989, p. 132) showed two ledges of conglomerate/sandstone separated by 9 m of mudstone at the top of the Chinle section in this area. However, she missed a fault repeat; the lower of these two ledges is a gravity slide block equivalent to the upper ledge. A fault that strikes NW separates the two blocks in the SE1/4 NW1/4 sec. 1T12N, R4E. The Correo Member is also well exposed about 0.9 km to the SE in the SW1/4 NE1/4 SW1/4 sec. 6, T12N, R5E (our section F) where it yields fragmentary Late Triassic vertebrate fossils (see below). The Middle Jurassic Entrada Sandstone disconformably overlies the Correo Member in the Placitas area.

CEDAR CREST

Triassic strata are exposed in two outcrop belts in the Cedar Crest area on the southeastern flank of the Sandia uplift: from northwest of Tijeras to beyond Calfoncito in T10-11N, R5E on the dip slope of the Sandia Mountains; and east of San Antonio in secs. 20-21, 28-29, and 33, T11N, R5E on the northeastern flank of the Tijeras syncline. Outcrop quality in these two belts is poor due to soil and vegetation cover. Because of this, we did not measure a complete section of the Triassic strata. Instead, we measured three short sections and made stratigraphic observations at other localities (Appendix 1). These indicate the Triassic section in the Cedar Crest area is very similar to that in the Hagan basin with one important exception the Correo Member of the Petrified Forest Formation is absent in the Cedar Crest area.

The basal unit of the Triassic section in the Cedar Crest area is the Anton Chico Member of the Moenkopi Formation. It is well exposed at our section 1 (SW1/4 NE1/4 sec. 15, T10N, R5E) where 11.2 m of red Moenkopi sandstone and siltstone disconformably overlie the San Andres Formation and are disconformably overlain by the Agua Zarca Formation (Fig. 3). Moenkopi strata here are gray to pale red; sandstones are ripple-laminated litharenites. To the north of the Hobbies section and throughout the Cedar Crest area, Moenkopi strata are very poorly exposed, usually underlying a covered slope between San Andres and Agua Zarca hogbacks.

The base of the Chinle Group in the Cedar Crest area is the Agua Zarca Formation. We were not able to measure a complete thickness of the Agua Zarca Formation here, but estimate its thickness from Kelley's map 1) mapping as 108 m thick that we assign to the Agua Zarca Formation. Previous workers identified this unit as the Santa Rosa Sandstone (or Formation), but it is more similar to the Agua Zarca, particularly in the absence of a medial mudstone member, which is characteristic of the Santa Rosa to the east. Agua Zarca conglomerates contain significant amounts of extrabasinal clasts of quartzite and Paleozoic limestone. Sandstones are mostly sublitharenites and quartzarenites; dominant colors are gray and yellowish gray. Petrified logs are common at some Agua Zarca outcrops. The unit tends to form hogbacks.

Salitral Formation

About 92 m of mostly gray and purple bentonitic mudstones and intraformational conglomerates overlie the Agua Zarca Formation in the Hagan basin. These strata are tentatively assigned to the Salitral Formation, which they lithologically resemble. Because of poor exposures, their presence in the Placitas and Cedar Crest areas cannot be confirmed.

Petrified Forest Formation

A thick (260 m) section of mostly reddish brown bentonitic mudstones caps the Triassic section around the Sandia uplift. We assign these strata to the Petrified Forest Formation. A prominent ledge of conglomerate and sandstone, as much as 37 m thick, is at the top of the Petrified Forest Formation in the Hagan basin and Placitas area and is assigned to the Correo Member. The Middle Jurassic Entrada Sandstone disconformably overlies the Petrified Forest Formation around the Sandia uplift.

PALEONTOLOGY

Very few fossils of biostratigraphic significance are known from the Triassic strata around the Sandia uplift. Known occurrences are:

1. Indeterminate bone fragments and coprolites are present in the Moenkopi Formation in the Hagan basin in the NW1/4 NW1/4 NW1/4 sec. 25 (unsurveyed), T13N, R5E.

2. Fossil logs are common locally in the Agua Zarca Formation, and Lucas (1991, fig. 4C) illustrated one of these logs in the NE1/4 SW1/4 sec. 36, T13N, R5E. These logs are of no biochronological significance except that they are common in basal sandstone/conglomerate complexes of the Chinle Group (Shinarump, Agua Zarca, Santa Rosa formations).

3. In the Department of Geology of the University of New Mexico, there is a specimen of Otozamites powelli from the "Santa Rosa Sandstone" in the Hagan basin, but no more precise locality data are available. Otozamites powelli is a common constituent of Ash's (1980) Dinofyton floral zone of late Carnian age.

4. Indeterminate reptilian bones (NMMNH 22433) and large metoposaurid bones (see Lucas, 1991, fig. 4D) are present in the Salitral Formation in the Hagan basin at NMMNH locality 3029 at UTM 3906130N, 376140E, zone 13.
5. Poorly preserved unioiid bivalves are present in the Petrified Forest Formation near Placitas at NMMNH locality 845 in the SE1/4 SE1/4 NW1/4 SE1/4 sec. 1, T12N, R4E.

6. The Correo Member of the Petrified Forest Formation produced vertebrate coprolites, unioiids, phytosaurs, the amphibian Apachesaurus and possible Typothorax (Lucas, 1991, fig. 6) from NMMNH localities 220, 251, 252, and 3028 in the Hagan basin; 250- SW1/4 sec. 5, T12N, R6E; 251- NE1/4 NE1/4 sec. 1, T12N R5E; 252- sec. 13, T13N, R5E; 3028- NW1/4 SE1/4 sec. 12, T12N, R6E. In the Placitas area, the Correo Member produced phytosaur (NMMNH P-22434) and large metasaur (NMMNH P-22435) bones at NMMNH locality 3030 at UTM 3906600N, 367630E, zone 13.

The above listed fossils suggest that the Agua Zarca and Salitral? formations are of late Carnian age, whereas the Correo Member is Norian. They thus support the correlation of Triassic strata around the Sandia uplift with nearby Triassic strata advocated here (Fig. 5).

CORRELATION

Correlation of the Triassic section exposed around the Sandia uplift with Triassic strata exposed along the southern Colorado Plateau to the west and to the east along the southern High Plains (Fig. 5) has already been discussed in detail by Lucas (1991, 1993) and Hunt and Lucas (1993). This correlation is primarily based on lithostratigraphy, supplemented by and consistent with the limited Triassic paleontology available from the Sandia uplift.

ACKNOWLEDGMENTS

Bruce Allen, Steve Hayden, and Mike Space assisted with fieldwork. The owners of the Diamond Tail Ranch generously granted access to their property. O. J. Anderson and A. P. Hunt reviewed the manuscript.

### Chinle Colors and Lithologies: Clasts

- Basal: red mudstone with some light-colored grayish pink (5G7/4); variegated moderate red sandstone (5R8/4) and pale purple (5P6/2), light greenish gray (5GY8/1), and medium gray (5N5/6); both are very calcareous.
- Cross fault so dip changes to 40°, lower 1.5 m of unit 16 equals unit 13.
- Silty mudstone: light greenish gray (5GY8/1) to pale grayish yellow (10YR8/2) and grayish yellow (5Y8/4); bentonitic; calcareous.
- Bone-bearing conglomerate: grayish red (10R4/2) to pale reddish brown (10R5/4); clasts are primarily intraformational calcareous nodules with occasional mudstone rip-ups; extremely calcareous; upper 5.3 m is sandstone: light olive gray (5Y6/1) with flecks of pale yellowish orange (10YR8/6); fine-grained, subangular, moderately well-sorted litharenite; ripple laminated; some planar crossbeds at top of unit; caps low benches; calcareous.
- Mudstone: grayish red (5R4/2) and grayish red purple (5RP4/2); some light-colored grayish pink (5R8/2) splotches; very calcareous.
- Mudstone: same color and lithology as unit 22.4.
- Silty sandstone: grayish red (5R4/2); fine- to medium-grained, subrounded, poorly sorted sub litharenite: very low angle crossbeds: largely covered; calcareous.
- Mudstone: same color and lithology as unit 22.4.
- Sandstone: pale reddish brown (10R5/4); fine- to medium-grained, subangular, moderately well-sorted litharenite: lenticular; same thin mudstone interbeds; calcareous.
- Mudstone: same color and lithology as unit 22.4.
- Sandstone: pale reddish brown (10R5/4); fine- to medium-grained, subrounded, well-sorted sublitharenite: very low angle crossbeds: largely covered; calcareous.
- Mudstone: same color and lithology as unit 22.4.
- Sandstone: pale reddish brown (10R5/4); fine- to medium-grained, subrounded, well-sorted sublitharenite: low angle trough crossbeds; calcareous.
- Mudstone: same color and lithology as unit 22.4.

Chinle Group:
Agua Zarca Formation:
7 Sandstone; pale greenish yellow (10YR/2) to yellowish gray (5Y/7):
2.3; fine- to coarse-grained layers of angular, moderately well-sorted, quartzarenite; quartz cement; slightly calcareous; laminated and trough crossbedded.
6 Conglomerate and conglomeratic sandstone; light olive gray (5Y/7):
2.0 to yellowish gray (7Y/7) to medium gray (5Y/5); clasts are cherts, quartzite and mudstone rip-ups, many of which are weathered to voids; matrix is quartzose sandstone; calcareous.
5 Sandstone; moderate olive brown (5Y/4-4) to dusky yellow (5Y/6):
1.0; fine-grained, subrounded, well-sorted sublitharenite; calcareous; laminated.
4 Sandstone and conglomerate sandstone; olive gray (5Y/3):
2.0 to light olive gray (5Y/5):
coarse- to very coarse-grained; rounded; moderately well-sorted; well indurated; few conglomeratic clasts are 2-3 mm in diameter; very calcareous; trough crossbedded.
3 Conglomerate; yellowish gray (5Y/7):
2.0 to light greenish gray (5GY/1-1); clasts are dominantly medium gray (5Y/5) to black (N1) mudstone blocks; matrix is coarse-grained, subangular, well-sorted quartzarenite; not calcareous; trough crossbeds.
2 Sandstone; moderate reddish brown (10R4/6): sublitharenite; fine- to medium-grained; laminated.
1 Conglomerate; moderate reddish brown (10R4/6); clasts are Moenkopi mudstone and silstone; laminated.

Section H: Placitas samples

Due to cover and structural complexities we did not measure a complete stratigraphic section of the Chilie Group in the vicinity of Placitas. We have, however, sampled representative lithologies of the Moenkopi Formation and Chilie Group.

Moenkopi Formation: (NE 1/4 SW 1/4 SE 1/4 sec. 1 T12N R4E).

Sandstone: pale reddish brown (10R5/4); fine- to medium-grained, rounded, well-sorted sublitharenite; calcareous; some interbeds of mud- and siltslones of the same colors.

Conglomerate: medium gray (N5) to medium light gray (N6) fresh; stained to moderate reddish orange (10R6/6); clasts are well-rounded intraformational mudstone rip-ups that vary from 2 to 55 mm in diameter and are of typical Moenkopi lithologies and colors; very calcareous.

Unionid bed; Siltslone and silty mudstone; weathers pale reddish brown (10R5/4), medium dark gray (N4) to dark gray (N3) fresh; numerous complete but distorted and/or recrystallized unionids; very calcareous.

Section I

Section measured near Cedar Crest from the NW 1/4 NE 1/4 sec. 15 to NE 1/4 NE 1/4 sec. 15 T10N R5E. Section is overturned, with strata dipping 62° to N37°W.
SANDIA TRIASSIC

litharenite; calcareous; much covered. 28.0+
unconformity (Tr-3 unconformity of Pipringos and O'Sullivan, 1978):
Moenkopi Formation:
Anton Chico Member:
3 Silstone (lower 8.4 m) and sandstone (upper 2.5 m); medium
gray (N5) to pale red (5R6/2); very fine-grained, subangular,
poorly sorted litharenite; ripple laminated; calcareous; interbedded
with silty mudstone of identical colors. 10.9
2 Sandstone; grayish yellow green (5GY7/2); muddy; friable;
medium-to coarse-grained, subangular, poorly sorted sub-
litharenite; calcareous. 0.3
unconformity:
San Andres Formation:
1 Limestone; medium dark gray (N4); muddy, micritic with very
minor crinoid stems; some thin (1 mm or less) calcite veins. not
measured

Section J
Strata dip 42° to N80°E. Measured 9 August 1988 by S.G. Lucas and S.N.
Hayden in the SW¼ SW¼ NW¼ of sec. 36, T11N R5E Bernalillo County.

Section L: Miscellaneous samples in vicinity of Cedar Crest
Locations: A: Sandia Knolls, NW¼ SW¼ SW¼ sec. 21 T11N R6E. B: NE¼ NE¼ SE¼ sec. 24 T11N, R5E, on road west of Antonito. C: NW¼ SE¼ NW¼ sec. 28 T11N R6E along NM-44.

Descriptions:
A. Agua Zarca Formation: Sandstone; grayish yellow (5Y8/2) to yellowish gray (5Y7/2); fine- to medium-grained, rounded, well-sorted quartzarenite; well-indurated quartz cement; not calcareous.
B. Agua Zarca Formation: Sandstone; pale greenish yellow (10Y8/2) fresh, weathers to grays and blacks; medium-grained, subrounded, well-sorted sublitharenite; very well indurated; quartz cement; not calcareous.
C1. Petrified Forest Formation: Muddy sandstone; grayish red (10R4/2) to pale reddish brown (10R5/4); fine-grained, subangular, moderately well-sorted litharenite; weakly calcareous.
C2. Petrified Forest Formation: Sandstone and mudstone-pellet conglomerate; sandstone and matrix are light olive gray (5Y6/1); clasts are grayish red (10R4/2); sandstone varies from fine-grained, subangular, moderately well-sorted litharenite to coarse-to very coarse-grained, subangular, moderately poorly sorted litharenite; calcareous.
