Abstract:

Reward choice – employees’ ability to exercise control over the formal rewards they receive from work – is an important part of many HRM strategies. Reward choice is expected to increase employee performance, but conflicting findings highlight the need to better understand how and when it will do so. Based on fairness heuristic theory, we predicted that procedural justice mediates reward choice's influence on performance, and that choice attractiveness moderates that influence. A field study and an experiment both had similar results, supporting our predictions. Reward choice can increase performance by as much as 40 per cent, but only when the available choices are attractive to employees.

**Keywords:** choice | organisational justice | employee performance | rewards

Article:

**Introduction**

An increasingly popular HRM strategy is giving employees reward choice, which provides employees with the ability to choose the level or type of rewards they receive from work (Miceli and Heneman, 2000; White, 2009; IOMA, 2011). In the US, for example, fewer than 20 major employers allowed workers any control over how they were rewarded in 1980 (Hewitt Associates, 1993), but almost all major employers were offering some reward choice by 2007 (Employee Benefits, 2007). The use of reward choice in other countries shows the same increasing trend (Rao, 2008; Koo, 2011). Allowing employees to exercise some control over the nature of their rewards has become an important part of many organisations' HRM strategy.

Organisations appear to have embraced reward choice for two reasons: to control costs by only providing those rewards that employees actually value, and to benefit from improvements in
workers' attitudes and behaviour (Kelliher and Anderson, 2008; Lovewell, 2010). The use of choice reflects the fact that the traditional approach of offering standardised rewards has not succeeded in controlling costs or enhancing performance; such generic reward plans have tended to produce poor results (Beer and Cannon, 2004; Chiang and Birtch, 2006). Reward choice allows organisations to provide rewards that are customised to the individual, and is believed to help when competing to recruit and retain the best employees, as well as contributing to their subsequent performance (Fay and Thompson, 2001; Koo, 2011; Nazir et al., 2012). Consistent with the belief that reward choice benefits the worker and the organisation, scholarship has linked reward choice with both increased task performance and performance-related attitudes, such as organisational commitment (Lawler and Hackman, 1969; Cooper et al., 1992; Cole and Flint, 2004).

However, despite the widespread use of reward choice and research evidence of its effect on performance, two important gaps remain in the literature. The first gap concerns the mechanism linking reward choice to performance, which has remained unknown. The second gap concerns anecdotal and empirical evidence suggesting that employers do not always get a positive response from introducing reward choice (Sullivan, 2009; IOMA, 2011; Shreeram, 2012). While some studies have found a positive relationship between reward choice and performance (Lawler and Hackman, 1969; Cooper et al., 1992), at least one study (Morgeson et al., 2001) found that reward choice was not beneficial. It seems that reward choice can improve employee performance, but does not always do so. As such, the crucial next step for theory and practice lies in understanding how reward choice affects performance, including the mediating mechanism and boundary conditions.

In service of this goal, we report two studies that answer the two research questions: What is the mediator of the relationship between reward choice and work performance? and What are the boundary conditions of this relationship? Study 1 used a field survey to extend previous research by showing that reward choice influences performance-related attitudes through the mediating mechanism of procedural justice. Study 2 used an experimental design to replicate the Study 1 findings and to examine boundary conditions for reward choice. Study 2 found that reward attractiveness is an important moderator of the effect of reward choice (i.e. reward choice only increases justice and performance if the available choices are attractive).

Theoretical Background and Hypotheses

To study the relationship between reward choice and performance, we used the total rewards perspective (Nazir et al., 2012; Lin et al., 2014). This perspective defines rewards to include all of the valued outcomes that employees derive from their work, including base pay, incentives, non-salary benefits and perquisites (Fay and Thompson, 2001; Gross and Friedman, 2004; Chiang and Birtch, 2006). Focusing on an employee's total rewards is consistent with larger trends in the study of HRM, which are recognising the need to move towards more holistic views (Boxall, 2013). The total rewards perspective is based on the fact that different employees value different types of rewards (Kinnie et al., 2005; Krausert, 2014), but their response to having their desires satisfied will be similar. For example, imagine one worker who desires more pay, and another who is most concerned with flexible work arrangements. Giving both workers the same reward (e.g. more pay) would provoke differing responses, but if each worker is given what s/he
desires, s/he should have similarly positive responses (Cable and Edwards, 2004). The total rewards perspective focuses on compensation practices in general, so as to accommodate such diversity in the workforce.

Reward choice and performance

Organisations are increasingly offering customised total rewards by allowing workers to control some aspects of the level or type of rewards they receive. The specifics of the reward choice vary from simple forms such as choosing among different package options to situations where an employee's entire reward package is idiosyncratic (e.g. Anand et al., 2010). Providing employees with reward choice is expected to reduce organisational costs, increase worker satisfaction and improve worker performance (Kelliher and Anderson, 2008; Lovewell, 2010). The first two effects of reward choice – reduced cost and increased reward satisfaction – are straightforward. It has been documented that introducing reward choice decreases the cost of reward provision while simultaneously increasing workers' satisfaction (Karoly and Panis, 2004; Dencker et al., 2007).

Beyond these two effects, however, there is some evidence that reward choice can also improve performance. For example, one study found that workers who designed their own reward system performed better than workers who had an identical reward system imposed on them (Cooper et al., 1992). Cooper et al. (1992) speculated that reward choice will increase performance when rewards are perceived as fair, and that having workers involved in designing the reward system leads to perceptions of fairness.

Other findings also fit with the hypothesis that reward choice promotes perceptions of fairness. One study showed that workers perceived a reward system as less fair, less responsive, less motivating and less satisfying when that system was created exclusively by management, rather than through a joint management–union effort (Schwarz, 1989). Similarly, another study found that allowing workers to design their own reward system made workers more trusting of management (Jenkins and Lawler, 1981).

In contrast, however, one study failed to find any benefit from designing a new reward system (Morgeson et al., 2001): workers were extensively involved in providing information about reward preferences to management, but showed no positive response to the new rewards. Although Morgeson et al. (2001) admitted surprise at this outcome, we submit that it reflects the difference between choice and participation (Leana et al., 1990). In most studies of reward choice, the comparison is between one group of workers who designed their own reward system and another group of workers who had a system imposed on them. As such, these studies confounded participation (i.e. having voice or giving input about preferred options) with choice (i.e. making the actual reward selection). The studies that found positive responses compared ‘participation + choice’ to ‘no-participation + no-choice’. In contrast, Morgeson et al. (2001) compared ‘participation + no-choice’ to ‘no-participation + no-choice’: some workers in their study gave input, but the final system was chosen by management. That Morgeson et al. (2001) found no positive outcomes suggests that workers respond to choosing their rewards, rather than to participating in a process where someone else ultimately chooses. Choice is the key factor.
Additional evidence for the importance of choice was provided by a field experiment where some autonomous work groups were able to design their own reward plan, while control groups had an identical plan imposed on them by management (Lawler and Hackman, 1969). The initial results of Lawler and Hackman's (1969) field experiment were consistent with other work in this domain, showing that workers in the reward choice condition significantly increased their performance-related behaviours while those in the control (no choice) condition did not. While this design initially was like others in confounding participation and choice, a longitudinal component of the study indirectly separated the two elements.

Follow-up data collected by Scheflen et al. (1971) a year after the reward redesign revealed two important findings. The first finding was that the behavioural change lasted for a year; it was not a short-term result. The second finding was that losing the chosen reward system reversed the benefits associated with it. After the first year, management at the organisation discontinued the worker-designed reward plan. However, the removal of the plan did not reduce workers' rewards; in fact, management raised overall compensation levels, so that workers were making more than they were under the employee-designed plan (Scheflen et al., 1971). Nonetheless, when the reward system changed, performance behaviours reverted to pre-experiment levels. The study did not measure the mechanism involved, but when considered with the results of Morgeson et al. (2001) it seems likely that losing the feeling of choice was crucial. The change was not caused by the level of reward, since the workers' rewards actually increased when their plan was removed. The element that changed was that the workers no longer had a reward plan they had chosen for themselves.

In summary, it is clear that allowing workers to design their own reward system can improve performance. Furthermore, the evidence suggests that the choice exercised in system design is the key to increasing worker performance (Fang and Gerhart, 2012). Changes in the level of rewards do not account for observed performance gains, nor is it sufficient to participate in the design if someone else chooses what rewards are received.

An important limitation of previous studies is that they examined choice in the context of employees designing their own reward system. Obviously, such complete system design involves a sweeping change, and of necessity cannot occur often. Nonetheless, the underlying mechanism of positive responses to choice suggests that performance should be improved even if reward choice is less sweeping than designing the entire system. We, therefore, propose the constructive replication hypothesis that reward choice will increase performance, regardless of the scope of change.

Hypothesis 1: Reward choice increases worker performance.

Reward choice, procedural justice and performance

Stating the hypothesis that reward choice will increase performance begs the question of why. Drawing on fairness heuristic theory (Lind, 2001; Lind et al., 2001), we posit that procedural justice is the mediating mechanism linking reward choice to worker performance. We begin by defining procedural justice, and then use fairness heuristic theory to explain why reward choice will increase procedural justice and why procedural justice will increase performance.
Organisational justice is defined as an individual's perception of fairness in an organisation (Lind and Tyler, 1988), and while multiple types of justice have been found (Colquitt et al., 2012) the most relevant to reward choice are distributive justice and procedural justice. Distributive justice refers to workers' evaluation of whether the results of a decision are fair (Konovsky, 2000). For example, workers may judge whether the organisation is contributing an appropriate amount towards their retirement savings. In contrast, procedural justice concerns workers' evaluation of the process used to reach an outcome, distinct from the outcome itself (Thibaut and Walker, 1975). In the retirement contribution example, procedural justice would involve workers' views about the fairness of how contribution amounts were calculated (e.g. more for employees with greater seniority, maximum amount limits).

Procedural justice is usually more important than distributive justice (Colquitt, 2001). That is, workers will often accept a relatively poor outcome if they believe it was produced by a fair process (Van den Bos et al., 2001). Moreover, one of the key contributors to perceptions of fair process is the power to choose (Lind et al., 1990; Korsgaard and Roberson, 1995). As a result, procedural justice should be the most important issue in the context of reward choice. Indeed, prior study has shown that reward choice contributes to perceptions of justice in the reward system (Cole and Flint, 2004). In other words, if employees can choose their rewards, they will perceive those rewards as more procedurally just.

Furthermore, fairness heuristic theory suggests that workers' perceptions of the reward system's fairness will generalise to their perception of the organisation as a whole (Lind, 2001; Lind et al., 2001; Mignonac and Richebe, 2013). Fairness heuristic theory explains that particular occasions of fair treatment lead individuals to assume that those occasions reflect the overall level of fairness in the organisation. If the organisation acts justly in important and salient situations, then the individual will tend to assume that the organisation is fair in general. Because of how important rewards are to workers, judgements about the fairness of the reward system should be particularly influential in shaping overall perceptions of the organisation. As such, reward choice should contribute to generalised perceptions of procedural justice among workers: having reward choice will lead to perceptions of justice in the reward system, and evaluations of the reward system will be generalised to the organisation as a whole (Thibaut and Walker, 1975; Tyler, 1987).

Workers who believe their organisation is procedurally just subsequently believe that there is greater interpersonal trust between themselves and the organisation, and that trust motivates them to behave in a cooperative and supportive fashion (Lynch et al., 1999; Cropanzano et al., 2001). Individuals who feel fairly treated take more action to support the common good (Tyler and Blader, 2003). When workers believe their organisation is just, they are more willing to contribute (Grover and Crooker, 1995; Lind, 2001) and their contributions improve performance (Konovsky, 2000; Colquitt et al., 2012). As such, procedural justice should be the mechanism by which reward choice increases performance.

*Hypothesis 2: Procedural justice mediates the effect of reward choice on worker performance, such that reward choice increases procedural justice and procedural justice increases worker performance.*
Choice attractiveness: a boundary condition

Given the evidence that having choice increases perceptions of justice (Lind et al., 1990; Korsgaard and Roberson, 1995), one might assume that any reward choice would increase justice and subsequent performance. However, research in psychology shows that offering choice does not always produce positive responses (Chua and Iyengar, 2006). For example, Botti and Iyengar (2004) found that if individuals could only choose among meal options that they found unappealing, the freedom to choose actually reduced their satisfaction with the meal. Extending these results to the domain of work rewards suggests that not any choice will do; the available options must be attractive to workers.

For example, imagine an organisation that offers only unsatisfactory reward choices to employees. While the workers will be able to exercise reward choice, there is no reason to think that doing so will improve their perception of the reward system in this hypothetical organisation. Being compelled to choose among a series of unattractive options will not contribute to perceptions of procedural justice, and is more likely to focus employee attention on the poor level of their benefits (Colquitt, 2001). Since perceptions of an organisation's overall justice depend on perceptions in specific circumstances, the organisation that only offers choice among unattractive options will not be perceived as more procedurally just in general. Since the performance gains associated with reward choice derive from generalised perceptions of procedural justice, offering reward choice among unattractive options will therefore fail to improve performance. Consistent with this prediction, media reports have noted some overtly negative responses to reward choice (Shreeram, 2012). Offering reward choice does not guarantee positive results; it is necessary to offer attractive choices.

Hypothesis 3: Choice among unattractive rewards does not increase procedural justice.

Hypothesis 4: Choice among unattractive rewards does not increase work performance.

Study 1

Method

Sample and procedure

One hundred full-time workers were randomly selected from the alumni database of a large Midwestern American university master's programme and invited to complete an online survey. Forty-six workers provided usable responses, representing a range of industries and job functions. The respondents were primarily young professionals (mean age = 30.47 years, SD 6.02). All had graduate-level education, and most had recently been promoted (mean job tenure = 2.30 years, SD 1.63; mean organisational tenure = 4.11 years, SD 3.79); 57 per cent of the participants were male. More than half (54 per cent) had supervisory duties (mean number of subordinates = 6.47, SD 17.07).

Variables
To measure reward choice, respondents were asked to describe the two most important rewards they received from their employer. For each of those rewards, they reported the extent of their reward choice in terms of degree of choice, satisfaction with degree of choice and quality of available choices on five-point scales. We combined these six items (three items × two rewards) into a reward choice measure that had good internal consistency (α = 0.80, 95 per cent CI [0.59, 1.00]).

Because objective performance measures would not be comparable across our sample, we used affective organisational commitment (Meyer et al., 1993) as a proxy measure for performance (six items, e.g. “I really feel as if this organisation's problems are my own”). Affective organisational commitment refers to a psychological state of positive attitudes towards continuing one's relationship with an organisation; workers are affectively committed to an organisation to the extent that they identify themselves with that organisation and feel an emotional attachment to their membership (Meyer and Allen, 1991). Affective organisational commitment is not a measure of performance, but it is the type of commitment most strongly associated with performance (Meyer et al., 2002), and meta-analysis has revealed a consistent positive relationship between affective commitment and performance (Riketta, 2002). In particular, when individuals are relatively new to their job – as was the sample used here – the meta-analytic correlation between affective commitment and performance is 0.44 (Wright and Bonett, 2002). Moreover, organisational commitment has been shown to mediate the relationship between rewards and performance (Park and Kruse, 2014).

Participants also completed Colquitt’s (2001) scale measuring procedural justice (seven items, e.g. “To what extent are the procedures use in the organisation free of bias?”), as well as items about their demographic characteristics. In addition, to control for different levels of rewards among participants, we had them report their overall satisfaction with the perceived value of the rewards provided by their employer (benefit level, four items, e.g. “How satisfied are you with the value of your benefits?”; Williams et al., 2008).

Results and discussion

Based on responses to demographic questions, respondents did not appear to differ from non-respondents. Demographic characteristics largely proved to be non-significant control variables, and even when they were significant their inclusion did not change any of the substantive conclusions. As such, demographic variables were excluded for clarity and parsimony (Aguinis and Vandenberg, 2014). Descriptive statistics are provided in Table 1.

We used ordinary least squares regression for our primary analyses. Consistent with Hypothesis 1, reward choice was related to affective organisational commitment (Model 1 in Table 2). Furthermore, consistent with Hypothesis 2, procedural justice mediated the relationship between reward choice and affective organisational commitment. Reward choice predicted procedural justice (Model 2), and when controlling for the relationship between procedural justice and affective organisational commitment there was no consistent relationship between reward choice and affective commitment (Model 3). To further assess mediation, we conducted two additional tests: a bootstrap estimation (Preacher and Hayes, 2008) revealed a standardised indirect effect of 0.23 (95 per cent CI [0.03, 0.46]), and a Sobel (1982) test found a significant effect ($z = 2.24, p = 0.02, 95$ per cent CI [0.04, 0.40]). All of these results are consistent with Hypothesis 2, the prediction that procedural justice mediates the relationship between reward choice and affective organisational commitment.

To provide a conservative test of our predictions, we also conducted several additional analyses. First, we estimated a model that included the control variable for how satisfied individuals were with their level of rewards (Model 4). This analysis revealed that the relationship between procedural justice and performance remained after controlling for the level of rewards. Second, we estimated alternative models using Huber, bi-square and sandwich corrections, which can improve model estimates in the presence of outliers or heteroscedasticity (Huber, 1981). In all cases, the results were substantively unchanged. Moreover, post hoc diagnostics revealed that collinearity was not a concern; the largest variance inflation factor was only 2.0 (O'Brien, 2007). Additionally, power analysis revealed an observed statistical power greater than 0.9, which exceeds the traditional 0.8 guideline required for appropriate hypothesis testing (Cohen, 1988). Taken together, all of these results suggest the robustness of the findings.

In sum, using a diverse sample of full-time workers, we found results consistent with prior research: reward choice was associated with higher levels of the performance-related attitude of affective organisational commitment. Also consistent with previous studies (e.g. Tremblay et al., 1998), the effect of reward choice was independent of the level of the reward. In addition to replicating previous results, these findings extended previous work in two important ways. First, where previous studies were conducted primarily with first-level workers, the majority of our respondents were managers or supervisors. The results, therefore, suggest that reward choice has similar effects across hierarchical levels. Second, our results showed that the effect of reward choice was mediated by procedural justice. This finding is consistent with the long-standing, but previously untested, prediction that reward choice improves performance by fostering perceptions of fairness.

Nonetheless, Study 1 had three limitations. First, it used affective organisational commitment as a proxy, rather than measuring performance directly. Second, it used cross-sectional data, which prevents us from ruling out alternative explanations (e.g. committed employees may be more likely to perceive the organisation as fair). And finally, the data did not allow a test of the moderating effect of choice attractiveness. Moreover, the reward choices that the respondents reported on were primarily non-salary benefits, rather than choice about pay. To address these issues, we conducted a second study in a controlled experimental context.

Study 2
Method

Sample and procedure

Eighty-two undergraduate business majors at a large Midwestern American university participated. Their mean age was 20.5 years (SD 1.61) and 47.5 per cent were male.

After providing consent, participants were told about the task and how they would be rewarded (i.e. the experimental manipulation); they then completed the procedural justice measure from Study 1, and finally completed the compound remote associates task (CRA). In the CRA, participants try to find one word that can be combined with each of three different prompt words to create meaningful compound terms. For example, the prompt ‘night/wrist/stop’ is solved by the word ‘watch’, which can combine with each of the three prompts. Participants were presented with 140 sets of prompts (Bowden and Jung-Beeman, 2003) and directed to complete as many as they could. The CRA was originally developed as a measure of creativity (Mednick, 1962), but recent research treats the task as an assessment of problem-solving ability that does not require domain-specific knowledge (Bowden and Jung-Beeman, 2003). As such, the CRA is considered a good measure of abstract knowledge-based work performance (Ackerman and Zalmanov, 2012).

Reward choice was manipulated as a three-level, between-subjects factor (attractive choices, less attractive choices, no choice), derived from a two-phase pretest. In the first phase of pretesting, a sample of 43 participants was shown a list of 14 possible rewards for completing an experiment, and asked to rate each reward's attractiveness. In the second phase of pretesting, a different sample of 31 participants rated the overall attractiveness of the three highest rated rewards from phase 1 (set A) and the three lowest rated rewards from phase 1 (set B). Set A was rated as significantly more attractive than set B, regardless of presentation order [M = 4.68 vs. 2.32 on a seven-point scale, paired t(31) = 8.56, p < 0.01].

The options in the attractive choices condition were the following: (a) two points of extra credit + $0.10 cash per correct answer; (b) two points of extra credit + $0.10 per correct answer donated to a charity of their choice; (c) $0.30 cash per correct answer (no extra credit); or (d) two points of extra credit (the university's standard experimental reward). The options in the less attractive choices condition were the following: (a) $0.20 cash per correct answer (no extra credit); (b) two points of extra credit + $0.13 in fast food coupons per correct answer; (c) two points of extra credit + $0.13 donated to the Humane Society per correct answer; or (d) two points of extra credit + $0.10 cash per correct answer. The first three of the less attractive options were the set rated least attractive in pretesting (i.e. set B); the fourth was the same as the first attractive choices option and was the single option judged most attractive in pretesting. We offered this single, highly attractive option with the three less attractive rewards to control for the effects of reward content, as described below.

After learning about the task, participants in the attractive choices and less attractive choices conditions chose their reward from the appropriate list. All but three of the attractive choices participants chose the same reward, and all of the less attractive choices participants chose that
same reward. Therefore, participants in the no choice condition were told that they would receive that reward: two points of extra credit + $0.10 cash per correct answer. To prevent any effect from reward content, the three participants who chose a different reward were not included in the data set (final n: attractive = 27, less attractive = 25, no choice = 30). As such, all participants operated under an identical reward structure; the only difference among groups was whether they had it imposed on them or chose it from a list of otherwise attractive or less attractive options.

Results and discussion

As in Study 1, demographic variables were non-significant covariates. The mean CRA performance was 30.8 correct responses (SD 17.88), the mean level of procedural justice was 3.92 on a five-point scale (SD 0.74), and these two variables were significantly correlated ($r = 0.25, p = 0.02$). Consistent with Study 1, reward choice increased performance [$F(2, 79) = 5.22, p < 0.01, \eta^2 = 0.12$] and procedural justice [$F(2, 79) = 4.54, p = 0.01, \eta^2 = 0.10$].

 Planned contrasts supported both Hypotheses 3 and 4-Hypotheses 3 and 4 (see Table 3). Participants in the attractive choices condition reported greater procedural justice (M = 4.26) than those in the no choice condition (M = 3.74; $t = 2.74, p < 0.01$), and greater procedural justice than those in the less attractive choices condition (M = 3.77; $t = 2.47, p = 0.02$). There was no significant difference in reported procedural justice between the no choice and less attractive choices conditions ($t = 0.15, p = 0.88$). As one would expect, given the mediating role of procedural justice, the results were similar for performance. Participants in the attractive choices condition (M = 39.26) performed 39.6 per cent better than participants in the no choice condition (M = 28.13; $t = 2.46, p = 0.02$) and 57.8 per cent better than participants in the less attractive choices condition (M = 24.88; $t = 3.04, p < 0.01$). There was no statistically significant difference in performance between the no choice and less attractive choices conditions ($t = 0.71, p = 0.48$).

*No choice n = 30, less attractive choices n = 25, attractive choices n = 27.*

CRA, compound remote associates.

In sum, reward choice increased performance and perceptions of procedural justice, but only when the choice was made from attractive options. These results extended our previous study's findings in three important ways. They replicated them in a different context, they generalised them to a different criterion variable, which was an objective measure of task performance, and they provided a clear demonstration of the causal effect of reward choice.

Providing one attractive option in the less attractive choices condition was necessary to control for the effects of reward content, but it may have led participants to perceive this condition as effectively offering no choice, since only one option was attractive. This could explain the comparable results between the less attractive choices and no choice groups. It may be that if the less attractive choices condition had offered only unattractive options, performance would have been reduced.
General Discussion

In two studies, we examined the relationship between reward choice and performance. Consistent with predictions, reward choice increased performance through the mediating effect of procedural justice. Workers provided with reward choice perceived their organisation as more fair, and that perception of fairness led to improved performance. Our results showed that the effect of reward choice on performance is independent of the actual level of reward, but does depend on choice attractiveness. Workers offered a choice among unattractive options did not perceive greater procedural justice nor did their performance improve; only those choosing from multiple attractive options had perceptions of greater procedural justice and subsequent performance gains. Our data combined experimental and field observations, showing consistency across diverse contexts, tasks and measures. As a result, our research design provides strong evidence for the causal effect of reward choice. These findings have important theoretical and practical implications.

Theoretical implications

The results make three theoretical contributions. The first is to demonstrate the previously uncertain mediator of the effect of reward choice on performance. HRM suffers from a lack of theoretical explanations for observed results (Monks et al., 2013) and poor evidence of the causal nature of observed associations (Guest, 2011). Our data address both of these issues. Prior to our research, there were no data on the mediated process by which reward choice influences performance. Allowing workers to create their own reward system had been shown to enhance performance (Lawler and Hackman, 1969; Cooper et al., 1992), but the explanation for this result remained unclear. We advanced this work by testing the effects of reward choice in different contexts, with different outcomes and different types of choice, while measuring the mediating mechanism. As a result, we extended and clarified those previous studies, confirming that perceptions of fairness – specifically of procedural justice – are the mechanism by which reward choice improves performance. Moreover, our use of both field and experimental data supports inferences of cause: choice is the causal agent.

The second contribution arises from clearly distinguishing between choice and participation (Barber et al., 1992). Previous studies confounded these two factors, which led to some apparently anomalous findings (Morgeson et al., 2001). Our results appear to resolve the anomaly, creating consensus in the literature. In our studies, workers had choice (i.e. they could decide what type or level of reward they received), but they did not participate in creating those choices. We found that choice improved performance, while previous studies found that the combination of choice and participation improved performance (Lawler and Hackman, 1969; Cooper et al., 1992). Combining these results with the observed lack of benefit among employees who had participation without choice (Morgeson et al., 2001) suggests that choice, not participation, is essential. As such, Morgeson et al.’s (2001) results are consistent with previous work, so long as one distinguishes between choice and participation. Nonetheless, opportunities remain for further investigation. While choosing among predefined options is sufficient to improve performance, future scholarship can investigate whether the benefits are greater when choice is combined with participation (Deci and Ryan, 2000).
The third contribution of our work is to highlight the complexities of choice, and thereby identify a significant boundary condition to the benefits of reward choice. Research in other contexts has shown that choice is not unequivocally regarded as good (Iyengar et al., 2004), and we likewise found that in the case of work rewards not any choice will do. Reward choice only improved performance when individuals perceived their choice options as attractive ones. As such, the preferences of workers will be an important consideration in future investigations of reward systems and reward choice. All choice options will not have equivalent effects, suggesting an important role for prechoice participation to ensure that choice options are attractive.

Practical implications

Our findings suggest several related considerations for implementation. In discussing these, it should be recalled that others found that the effects of reward choice persisted among employees for more than a year (e.g. Scheflen et al., 1971). In the long run, the performance-enhancing consequences of reward choice may be substantial, which makes this issue an important one.

The most salient element of our findings is that choice is sufficient to improve performance. Before our research, one might have inferred from the literature that performance gains required allowing employees to design their own reward system, which would be impractical in many contexts. Our results show that reward design is not necessary. It is enough for management to have workers choose among attractive options. Doing so improved performance in our study by almost 40 per cent, compared with workers who had no choice. However, reward attractiveness is an important contingency; there were no benefits from choice among unattractive options. Organisations must ensure that the rewards offered meet not only their own needs, but also those of the employees. It may be best to have workers participate in identifying reward options to ensure that the results are sufficiently attractive. In addition, whatever system is used, it will be crucial to evaluate it in terms of employee perception and response (Corby et al., 2005).

In addition, organisational assistance may be required for the successful implementation of reward choice. In practice, it will likely not be enough to simply provide choice. For example, many organisations have moved from defined benefit pensions to defined contribution plans, and while this move clearly gives workers more reward choice it may not contribute to their perceptions of organisational justice, particularly since prior work has shown that many individuals make poor choices for their retirement (Benartzi and Thaler, 2007). Workers may require help using their freedom to choose.

Conclusion

It seems obvious that the type of rewards provided would influence employees' attitudes and behaviour. Our findings support this intuition, but further demonstrate that rewards have an effect beyond just their level. We integrated and extended previous studies by showing that being able to choose how one is rewarded has potentially powerful implications for organisational outcomes. Providing workers with choice over their rewards can lead them to feel more fairly treated, and thus to provide better performance. This observation clarifies decades of prior
research and, we hope, provides a foundation and stimulus for future investigation of the interrelations among rewards, choice and worker performance.
