ABSTRACT:
We study the IR emission from flared disks with and without additional optically thin halos. Flux calculations of a flared disk in vacuum can be considered a special case of the more general family of models in which the disk is imbedded in an optically thin halo. In the absence of such halo, flux measurements can never rule out its existence because the disk flaring surface defines a mathematically equivalent halo that produces the exact same flux at all IR wavelengths. When a flared disk with height H at its outer radius R is imbedded in a halo whose optical depth at visual wavelengths is τ halo, the system IR flux is dominated by the halo whenever τ halo > 1/4 H/R. Even when its optical depth is much smaller, the halo can still have a significant effect on the disk temperature profile. Imaging is the only way to rule out the existence of a potential halo, and we identify a decisive test that extracts a signature unique to flared disks from imaging observations.

Key words: circumstellar matter — dust — infrared: stars — radiative transfer — stars: imaging— stars: formation—stars: pre-main-sequence

1 INTRODUCTION
Modeling the IR radiation of pre-main-sequence stars has traditionally involved “classic” geometrically-thin optically-thick disks. This approach fails to produce many features of observed spectral energy distributions (SED) in both T Tauri stars (TTS) and Herbig Ae/Be stars (Haebes). One way out of this problem is to supplement the disk emission with a surrounding optically thin halo (e.g. Butner, Natta & Evans 1994; Miroshnichenko et al 1999, MIVE hereafter). A simpler alternative was proposed by Chiang & Goldreich (1997, CG hereafter): The surface skin of any optically thick object is of course optically thin. The emission from the disk surface layer can become significant under certain flaring conditions, and CG present SED fits of a number of TTS purely in terms of flared disks. This proposal was extended to SED modeling of Haebes by Chiang et al (2001) and Natta et al (2001).

While the CG model successfully solves the SED problem with a simple physical explanation, recent high-resolution imaging observations of both TTS and Haebes reveal the presence of halos, ignored in the CG approach. Most striking is the case of GM Aur, a classical TTS whose SED modeling was presented as evidence of the success of the CG approach (Chiang & Goldreich 1999). Indeed, HST/NICMOS images by Schneider et al (2003) show a flared disk with radius of ∼300 AU, but they also reveal the presence of a surrounding tenuous envelope extending to a radius of ∼1000 AU. Using detailed Monte Carlo calculations, Schneider et al find that simplified models with flared disk without an imbedding halo fail to replicate the scattered light intensity pattern seen in the NICMOS images. The addition of a halo is essential for successful modeling of both the SED and the images. Similarly, HST and ground-based imaging by Stapelfeldt et al (2003) of the TTS HV Tau C show a nearly edge-on flared disk imbedded in a more extended nebulosity. From detailed model calculations Stapelfeldt et al find that although it is possible to fit the SED purely with a flared disk, the flaring is unreasonably large and such models do not reproduce the image adequately. They conclude that a flared disk alone is an inadequate model and that an additional, extended component to the circumstellar density distribution is needed to explain the observations. Finally, from detailed modeling of flared disk SED Kikuchi, Nakamoto & Ogoshi (2002) conclude that halos are necessary supplements in explaining flat-spectrum TTS. High resolution observations of Haebes give similar evidence for imbedding halos. Combining space- and ground-based observations of HD 100546, the nearest Herbig Be star, Grady et al (2001) resolve the disk, which extends to 5″ (∼500 AU) from the star and displays the elongation of inclined viewing with i = 49°. But they also find that the disk is imbedded in a more extended halo (∼10″ radius) that is roughly circular in shape and optically thin (background stars are visible through it). Polomski et al (2002) performed high-resolution ground-based observations of a sample of Haebes whose mid-IR emission was claimed to be disk-dominated by Hillenbrand et al (1992). They find instead that the emission is not confined to an optically thick disk but originates in a more complex environment that includes large, extended dust envelopes. From analysis of ISO data, Creech-Eakman et al (2002) conclude that only a subset of the Haebes they observe can be described purely in terms of the CG model (notably, E.I. Chiang is a coauthor of this study).
How can the SED of the same T-Tauri star, GM Aur, be fitted successfully with a flared disk both with a halo (Schneider et al. 2003) and without one (Chiang & Goldreich 1999)? Is it at all possible to distinguish between these two cases? What, if any, is the unique radiative signature of each component? Obviously, imbedding a disk in a tenuous halo with a very small optical depth is not going to affect its emission appreciably. At which stage then does the halo assume a significant role? Here we address these questions. In appendix A we derive general results for the emission from optically thin dust in an arbitrary geometry. We apply these results to the surface layers of flared disks in §2 and to halos in which the disks could be imbedded in §3.

2 FLARED DISKS

2.1 The CG layer and its equivalence to spherical halo

Chiang and Goldreich (1997) noted that the emission from the optically thin surface layer of an optically thick disk, which has been neglected traditionally, can become significant under certain flaring conditions. The stellar radiation penetrates to an optical distance $\nu a = 1$ along a direction slanted to the surface by angle $\alpha$ (figure 1). The optical depth of the corresponding skin layer along the direction $\hat{n}$ is $\alpha \nu$ at visual and $\alpha \nu q_o$ at wavelength $\nu$, where $q_o = \sigma_o/\sigma_V$ and $\sigma_V$ is the dust cross-section at visual. In the case of a flat thin disk whose inner radius is determined by dust sublimation, the grazing angle is

$$\alpha_{\text{flat}} = \frac{\alpha^*}{a}, \quad \text{where} \quad \alpha^* = \frac{4}{3\pi} \frac{R_s}{R_a}, \quad a = \frac{r_a}{R_a};$$

(1)

here $R_s$ is the radius of the star, $R_a$ is the dust sublimation radius (eq. [A1]) and $r_a$ is distance from the axis. Flaring is defined by the radial profile of the disk height $H (\ll r_a)$ or, equivalently,

$$\beta = \arctan \frac{H}{r_a} \approx \frac{H}{r_a}.$$

(2)

As is evident from figure 1, $\alpha = \gamma - \beta$ where $\tan \gamma = dH/dr_a$, therefore the grazing angle of a flared disk is

$$\alpha = \frac{a d\beta}{da}. $$

(3)

The CG surface layer serves as an effective optically thin disk atop the underlying optically thick disk core, and its flux is obtained from the volume integration listed in equation [A7]. In the case of face-on orientation, the optical depth of the CG layer obeys $\sigma_o \int n a dz = q_o \alpha$, therefore its flux at distance $D$ is

$$F_{\text{CG},\nu} = \frac{2\pi R_s^2}{D^2} q_o \nu \int B_o(T) \alpha da.$$

(4)

Since the temperature profile of optically thin dust depends only on distance from the radiation source, the geometry dependence of this expression enters only from the radial variation of the grazing angle $\alpha$ (reflecting the dust column variation). But other geometries can produce an identical expression. For example, in the case of spherical geometry the flux is controlled by the dimensionless density profile $\eta$ (equation [A8]) and the radial optical depth is $\tau_V = \sigma_o \int n a dr$. Denoting the optical depth at visual wavelengths by $\tau_V$, the flux is

$$F_{\text{ sph},\nu} = \frac{4\pi R_s^2}{D^2} q_o \nu \int B_o(T) \eta y^2 dy,$$

(5)

where $y = r/R_s$. Since $y$ and $a$ enter only as integration variables in the last two integrals, the two expressions are mathematically identical if

$$\eta \propto \frac{\alpha(y)}{y} \quad \text{and} \quad \tau_V = \frac{1}{2} \int \alpha dy.$$

(6)

A minor point is that $T$ in eq. [6] is strictly a function of $y = a \sqrt{1 + \beta^2}$ rather than $a$ (since temperature is controlled by distance from the star); this slight difference can be ignored because $\beta \ll 1$ everywhere in the disk.

Scattering can be treated similarly and produces the same result since the only difference is that $B_o(T)$ is replaced by $J_o = L_o/4\pi y^2$, another function of $y$ (see equation [A9]). Therefore, there is a complete equivalence between spherical halos and the CG surface layers of flared disks; either case defines a model with the other geometry and the exact same flux. Specifically, equations [A1] and [A6] show that a thin flat disk is equivalent to a spherical halo with $\eta \propto 1/y^2$ and $\tau_V = \frac{1}{2} \alpha^*$. In the case of a flared disk, equations [A2] and [A6] show that the CG layer will produce precisely the same flux as a spherical halo with

$$\eta \propto \frac{d\beta}{dy}, \quad \tau_V = \frac{1}{2} \left[ \beta(R_a) - \beta(R_s) \right];$$

(7)

in particular, the equivalent halo of a disk with flaring angle $\beta \propto 1/d^4$ has density distribution $\eta \propto 1/y^{2 + 1}$. And conversely—given a spherical halo, the flared disk with the same outer radius and

$$\beta(a) = \beta(1) + 2 \tau_V \int y \eta(y) dy$$

(8)

will produce the exact same flux from its CG-surface layer.

Each disk defines a mathematically equivalent halo. Although this equivalence was derived only for face-on viewing of the disk, it carries to most inclination angles since the flux from optically thin dust involves a volume integration (equation [A7]) and the observed fraction of the disk surface layer remains largely intact as long as internal occultation is not too significant. Similarly, the general analysis presented in appendix A shows that the spherical idealization is not essential for the halo geometry. The dust distribution can be flattened and even distorted into irregular shape before severely affecting the emerging flux.

These results resolve the paradox of successful SED fits for the same star, GM Aur, with a flared disk both with a halo (Schneider et al. 2003) and without one (Chiang & Goldreich 1999). The halo contribution to the flux can be absorbed into the disk component by readjusting the flaring law, enabling a successful SED fit without a
The fundamental reason for image distortion by inclination is that the same projected distance from the star corresponds to widely different locations on the surface of the disk. On that surface, contours of equal distance from the star are circles of radius \( r_a \). When viewed face-on from distance \( D \), each contour appears as a concentric circle of radius \( \theta_a = r_a / D \), as seen in the top image in figure 2. At inclination viewing angle \( i \) to the disk axis, the contour is no longer circular. Absent flaring, the contour becomes an ellipse centered on the star with major axis \( 2\theta_a \) and minor axis \( \theta_a \cos i \), aligned with the projection of the disk axis on the plane of the sky. Flaring raises the contour to height \( H = r_a \tan \beta \) above the equatorial plane (figure 1), and the star is shifted toward the observer along the minor axis by \( \theta_a \tan \beta \sin i \). A point on the contour at position angle \( \phi \) from the near side of the minor axis is observed at displacement \( \theta = \theta_a g(\phi) \) from the star, where

\[
g(\phi) = \left( \tan(\frac{\sin i - \cos \phi}{\sin^2 \phi})^2 + \sin^2 \phi \right)^{1/2}. \tag{11}\]

These contours are shown in the bottom image of figure 2. The off-center position of the star on the minor axis creates an asymmetry such that the far and near portions of this axis obey \( \theta_{\text{far}} / \theta_{\text{star}} = \cos(\beta - \phi) / \cos(\beta + \phi) \). Because \( \beta \) increases with \( \theta_a \), this asymmetry increases with distance from the star.

At observed displacement \( (\theta, \phi) \) from the star, a point on the surface of the disk is located at \( r \approx r_a = D\theta/g(\phi) \). At that point the optical depth of the CG layer toward the observer is \( \tau(\phi) = q_0 \alpha / o(\phi) \), where

\[
o(\phi) = \hat{n} \cdot \hat{c} = \cos \gamma \sin i \sin \gamma \cos \phi. \tag{12}\]

Therefore the scattering image obeys

\[
I(\theta, \phi) \propto \left( \frac{g(\phi)}{\theta} \right)^2 \frac{\alpha}{o(\phi)}. \tag{13}\]

In this expression, both \( \alpha \) and \( \gamma \) are determined at the location \( r_a = D\theta/g(\phi) \) on the disk surface. A power-law grazing angle \( \alpha \propto 1/r_a^p \) produces the image \( I(\theta, \phi) \propto [g(\phi)/\theta]^{2+p}/o(\phi) \). This expression and the resulting brightness contours explain the results of Monte Carlo scattering calculations for flared disks (Whitney & Hartmann 1992, Wood et al 1998). Figure 3 shows the scattering images at three viewing angles of a flared disk with the parameters suggested for AB Aur by Dullemond et al (2001).

The images produced at emission wavelengths are handled in complete analogy. The only change is the replacement of \( r^{-2} \) by the temperature \( T_e \), i.e., another function of \( r \), modifying the dependence of brightness on \( g(\phi)/\theta \).

### 2.2 Images

The brightness contours of face-on flared disks are concentric circles centered on the star. Inclined viewing changes the contours substantially. Consider the intensity of radiation scattered from the CG surface layer. It obeys

\[
I \propto \tau(\phi) \frac{r_a}{r^2} \tag{10}\]

where \( r \) is the distance to the star and \( \tau(\phi) \) the optical depth toward the observer at the scattering point (equation 12). Both factors introduce distinct image asymmetries.
Figure 3. Viewing at inclination angles \(i = 25^\circ, 45^\circ\) and \(65^\circ\) of radiation scattered off the surface of a flared disk with \(3''\) radius and constant grazing angle \(\alpha = 4.9^\circ\). For each \(i\), the left panel shows the image with brightness contours, the right panel the asymmetry factor \(A\) (equation 14) along three azimuthal directions, shown in the top left panel, whose angles are designated from the observer’s direction. The asymmetry parameter vanishes along the major axis \((\phi = 90^\circ)\) at all inclination angles and along any axis at \(i = 0^\circ\) and \(90^\circ\). For flat disks, \(A\) is identically zero at all inclination angles.

Figure 4. Geometry of the halo-imbedded-disk model: a flat geometrically-thin optically-thick disk extends from the stellar surface to radius \(R_d\). An optically thin spherical halo extends from the dust sublimation radius \(R_s\) to \(R_h\). The small pillbox at the disk surface serves as a Gaussian surface for flux conservation.

peak brightness position. Its systematic variation with azimuthal angle easily distinguishes it from deviations from the perfect geometry of idealized models or noise in the data. Each flaring profile produces its own characteristic signature \(A\). For example, it is easy to show that the constant grazing angle \(\alpha\) used in figure 3 gives \(A \approx \tan \beta \tan i\) along the minor axis. Therefore, measuring \(A\) determines the flaring profile once the inclination is determined from the eccentricity of the brightness contours.

3 HALO-IMBEDDED-DISKS

The results of the previous section show that flux calculations of a flared disk in vacuum can be considered a special case of the more general family of models in which the disk is imbedded in an optically thin halo. In the CG case the “halo” is the disk surface layer, fully determined from the flaring geometry. This layer provides the same IR emission and heating of the underlying optically thick core as its equivalent halo. Therefore, a study of the general halo-imbedded-disk problem contains every possible CG model of flared disks while also covering all cases in which the disk is indeed imbedded in a dusty halo whose optical depth exceeds the bound in equation 3.

Consider a star surrounded by a geometrically thin passive disk and a dusty halo (figure 4). We study the case of a flat disk and a spherical halo, simplifications that enable us to derive analytical results and broad conclusions that offer important insight. These simplifications do not cause any serious limitations. As noted previously, the halo geometry can be distorted considerably without much impact on the outcome. And because only the optically thick core of the disk enters into considerations, its only relevant property is its temperature distribution, the surface shape is immaterial. Indeed, Wolf et al (2003) present detailed model calculation of a flared disk imbedded in an envelope pinched around the equatorial plane, and their results fully conform to our conclusions.

The halo extends from the inner radius \(R_s\) to some outer radius \(R_h = Y R_s\). Thanks to scaling, instead of these radii we can specify the dust temperature on each boundary (see appendix A). The halo is fully characterized by its density profile \(\eta(y)\) (eq A8) and optical depth \(\tau_V\); only \(\tau_V \lesssim 1\) is relevant in TTS and Haebes since the star is always visible. Because of its potentially large optical depth, the disk can extend inside the dust-free cavity where its optical depth comes from the gaseous component. The geometrically-thin disk assumption implies that the disk temperature varies only with radius, vertical temperature structure is ignored. This temperature is calculated from radiative flux conservation through the Gaussian surface in the shape of a small pillbox shown in figure 4. Denote by \(\mathcal{H}\) the radiative flux entering the pillbox from above, including both the stellar and diffuse components. Then

\[
\sigma T^4 - 2\pi \int B_\nu(T)E_3(\tau_\nu^D) d\nu + \int \mu I_\nu e^{-\tau_\nu^D/\mu} d\Omega d\nu = \mathcal{H}, \quad (15)
\]

where \(E_3\) is the 3rd exponential integral, \(\tau_\nu^D\) is the disk vertical optical depth and \(\mu\) is the cosine of the angle from the disk normal.

© 2003 RAS, MNRAS 000 1–11
mal. The first two terms on the left are the disk contribution to the upward flux, the third is the contribution of local intensity transmitted upward through the disk. When the disk is optically thick at frequencies around the peak of \( B_\nu(T) \) \((\tau_\nu^D \gg 1 \text{ for } \nu \sim kT/h)\), the second and third terms can be neglected, leading to the standard expression for disk temperature (e.g. Friedjung 1985, Kenyon & Hartmann 1987). We assume this to be the case everywhere in the disk, an assumption that we check for self-consistency in all our model calculations.

With its temperature derived, the disk emission is calculated from \( B_\nu(T)[1 - \exp(-\tau_\nu^D/\mu)] \). Because the disk is optically thick around the Planckian peak at all radii, the self-absorption factor can be neglected in the calculation of the disk overall bolometric flux. Then \( F_{\text{disk}}(D, i) \), the disk flux observed at distance \( D \) and inclination \( i \), is proportional to \( \cos i \), reflecting the variation of projected area. This proportionality remains largely unaffected by the envelope attenuation because the short wavelengths, the main contributors to the bolometric flux, emanate from close to the star so that their pathlength is approximately isotropic. Denote by \( L_{\text{disk}} \) the disk contribution to the overall luminosity \( L \) and by \( L_{\text{halo}} \) the contribution of the (halo + attenuated stellar) spherical component. The corresponding flux components are then

\[
F_{\text{disk}}(D, i) = \frac{L_{\text{disk}}}{2\pi D^2} \cos i, \quad F_{\text{halo}}(D) = \frac{L_{\text{halo}}}{4\pi D^2}
\]

and the overall flux is

\[
F(D, i) = \frac{L_{\text{disk}}}{2\pi D^2} \cos i + \frac{L_{\text{halo}}}{4\pi D^2} \frac{1 + 2x \cos i}{1 + x}
\]

where \( x = L_{\text{disk}}/L_{\text{halo}} \). The standard “bare” disk has \( L_{\text{disk}} = \frac{1}{3}L \) (Kenyon & Hartmann 1987), therefore in this case \( x = \frac{1}{3} \). Larger fractions can occur when the disk is imbedded in a halo because of the heating effect of the diffuse radiation, discussed below.

We performed detailed model calculations with the code DUSTY (Ivezić, Nenkova & Elitzur 1999) which takes into account the energy exchange between the star, halo and disk, including dust scattering, absorption and emission. Because its optical depth is typically \( \tau_\nu \ll 1 \), the halo is transparent to the disk emission in all the calculations, so we neglect the disk effect on the halo. In all the calculations, the spectral shapes \( q_\nu \) of the grain absorption and scattering coefficients are those of standard interstellar mix, the sublimation temperature \( T_s = 1500 \text{ K} \). The spectral shape of the stellar radiation is taken from the appropriate Kurucz (1994) model atmosphere.

### 3.1 Temperature Profiles

The heating rate of a thin flat disk by the stellar radiation at \( r \gg R_s \) is

\[
\mathcal{H}_* = \frac{2F_\nu}{3\pi R_s a^3}
\]

where \( F_\nu \) is the stellar flux at \( R_s \) and \( a = r_s/R_s \), with \( r_s \) distance from the axis (Friedjung 1985). This result reflects the \( 1/a^2 \) decline of the stellar solid angle and the \( 1/a \) variation of the grazing angle, yielding disk temperature variation \( T \propto a^{-3/4} \). Natta (1993) noted that imbedding the disk in a dusty halo can significantly affect its temperature even at small halo optical depths (see also D’Alessio, Calvet & Hartmann 1997 for the effect of optically thick halos). With a simple model for scattering at a single wavelength she found that the disk temperature law becomes \( T \propto a^{-(1+\rho)/4} \) if the halo density profile is \( \eta \propto y^{-\rho} \).

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5.png}
\caption{Top: Temperature profiles of a disk when heated only by a central star with \( T_s = 10,000 \text{ K} \) (full line), and when imbedded in a spherical dusty halo with \( \tau_\nu = 0.1 \) or 1, as marked. The halo starts at dust sublimation \( T_s = 1,500 \text{ K} \) and its density profile is \( \propto r^{-2} \). The temperature profile of the halo is also shown in each case. Bottom: The fractional contributions of the halo and (attenuated) stellar components to heating of the disk.
}\end{figure}

Our calculations confirm this important point. Figure 5 shows the temperature profile for a disk around a \( T_* = 10,000 \text{ K} \) star when “bare” and when imbedded in a spherical halo with \( \eta \propto y^{-2} \) and \( \tau_\nu = 0.1 \) and \( 1^1 \). Even though a halo with \( \tau_\nu \) as small as 0.1 is almost transparent to the stellar radiation, it still causes a large rise in disk temperature. As is evident from the bottom panel, the halo contribution to the disk heating overtakes the stellar contribution inside the dust-free cavity and dominates completely once the dust is entered. Wolf et al (2003) present a similar figure for their model.

A dusty envelope with \( \tau_\nu = 0.1 \) intercepts only about 10% of the stellar luminosity while the disk intercepts 25% of that luminosity. So how can the halo dominate the disk heating? The reason is that direct heating of the disk by the star occurs predominantly at small radii. The disk absorbs more than 90% of its full stellar allotment within 10\( R_s \) while its entire remaining area, even though much larger, absorbs only 0.025\( L \). From equation (17) the halo starts at \( R_h \sim 100R_s \), where \( \mathcal{H}_* \) has already declined to \( \sim 10^{-6} \) of its value at the stellar surface. In contrast, the halo emission is isotropic, therefore half of the radiation it intercepts is re-radiated.
Vinković et al.

Figure 6. Sample SEDs for halo-imbedded-disks around stars with $T_\star = 10,000$ K. The halo starts at $R_s$ where $T_s = 1,500$ K and extends to $1,000R_\star$, with density profile $\eta$ and optical depth $\tau_V$ as indicated. The disk starts at the stellar surface and extends to the radius $R_d$ set by the edge temperature $T_d = 25$ K (see Table 1). Each SED is normalized with the bolometric flux $F_{bol} = F(D, i)$ of the appropriate viewing angle (see equation 16). Top row: The SED for pole-on viewing. Full lines denote the overall flux, dotted lines the spherical (halo + attenuated stellar) component and dashed lines the disk component. The thick dot-dashed line is the flux from a face-on "bare" disk in the absence of an imbedding halo. It is omitted in the other rows. Mid row: Same models viewed at inclination angle $i = 85^\circ$. Bottom row: Variation of the overall SED with viewing angle $i$. Results for $i < 70^\circ$ are barely distinguishable from $i = 0^\circ$.

And since $R_h \sim 100R_\star$, the halo dominates the heating at $a = 1$ for $\tau_V$ as small as 0.02 when $p = 2$. As $\tau_V$ increases, the halo dominance of the heating moves inside the cavity. There the halo heating remains approximately constant while the stellar heating varies as $a^{-3}$, therefore stellar heating dominates only at $a \lesssim (60\tau_V)^{-1/3}$, at larger distances the halo takes over. This explains the results presented in the lower panel of figure 5 as well as figure 9 in Wolf et al (2003).

The figure also shows the temperature profile of the halo. This profile is largely independent of $\tau_V$, varying roughly as $y^{-2/(4+n)}$ when the long-wavelength spectral shape of the dust absorption coefficient is $q_\nu \propto \nu^n$. The important property evident in the figure is that the disk is much cooler than the envelope at all radii at which both exist and can also contain cooler material in spite of being much smaller, with far reaching consequences for the system radiation.

\begin{align}
\frac{H_h}{H_\star} & = \frac{9\pi p - 1}{16} \frac{R_h}{R_\star} \frac{R_\star}{R_d} \tau_V.
\end{align}
\[ \tau_V = 0.1 \quad \tau_V = 1 \]

Table 1. Derived parameters for the models whose SEDs are presented in figure. The luminosity ratio of the components is \( x = \frac{f_{\text{disk}}}{f_{\text{sph}}} \), and the disk radius is \( R_d = Y_d R_s \), set from the requirement \( T_d = 25 \text{ K} \). A “bare” disk (\( \tau_V = 0 \)) has \( x = \frac{1}{3} \) and \( Y_d = 18 \).

3.2 SED

From equation (16), the fractional contribution of the disk to the overall bolometric flux is

\[ \rho = \frac{F_{\text{disk}}}{F_{\text{disk}} + F_{\text{sph}}} = \frac{2x \cos i}{1 + 2x \cos i}. \quad (20) \]

Face-on orientation gives the maximal \( \rho = 2x/(1 + 2x) \) and the standard “bare” disk, with \( x = \frac{1}{3} \), has \( \rho \leq \frac{2}{3} \). Introduce the normalized SED \( f_{\nu} = F_{\nu}/\int F_{\nu} d\nu \), with similar, separate definitions for the disk and spherical components of the flux. Then

\[ f_{\nu} = \rho f_{\nu,\text{disk}} + (1 - \rho) f_{\nu,\text{sph}}. \quad (21) \]

Since the disk flux obeys \( F_{\nu,\text{disk}}(i) = F_{\nu,\text{disk}}(0) \times \cos i \) for the range of parameters considered here, \( f_{\nu,\text{disk}} \) is independent of the viewing angle \( i \), and the entire \( i \)-dependence of the SED comes from the mixing factor \( \rho \).

Figure 6 shows sample SEDs for some representative models. The halos extend from \( R_s \) to \( 1,000 R_s \), with density profiles and overall optical depths as indicated. The behavior of SEDs for spherical shells was discussed in IE and since the halo emission is unaffected by the imbedded disk, the SEDs plotted in dashed lines need no further discussion. The disk, on the other hand, is strongly affected by the halo as is evident from contrasting each disk SED, plotted in long-dashed line, with what it would have been in the absence of a halo (dot-dashed line). The two curves are identical within the first bump around 1 \( \mu \)m, caused by the stellar heating. In the absence of a halo, the disk SED drops from that peak as \( \lambda F_\lambda \propto \lambda^{-4/3} \). However, halo heating of the outer regions of the disk generates the second broad bump of disk radiation, which is almost two orders of magnitude higher than the “bare” disk emission.

The halo heating effect is also evident from other disk properties. The disks in these models start at the stellar surface and extend to a radius \( R_d \) where the temperature is \( T_d = 25 \text{ K} \). In the absence of a halo, this temperature would be reached at \( Y_d = R_d/R_s = 18 \). As Table 1 shows, heating by even a tenuous halo with \( \tau_V = 0.1 \) pushes this radius out by almost factor 5 for the steep density profile \( r^{-2} \) and another factor of 2 for the flatter \( r^{-1} \) profile which spreads the heating further away from the star. The impact of halo heating increases with \( \tau_V \), pushing \( R_d \) further out still. Similarly, the disk luminosity, \( xL_s/(1 + x) \), is only 0.25\% in the absence of a halo but increases as the halo directs more radiation toward it to the point that it becomes 0.6\% when \( \tau_V = 1 \).

Although it is more compact, the disk can become the stronger emitter at long wavelengths so that the overall SED is dominated by the halo at IR wavelengths and by the disk at sub-mm and mm wavelengths. This role reversal affects also the wavelength behavior of images. Figure 6 shows a series of images at various wavelengths for a sample model. At IR wavelengths the image is dominated by the halo, displaying the size variation discussed in appendix A. The 0.6\% image is dominated by scattering, the \( \lambda \geq 5 \mu \)m images reflect dust emission, leading to size increase with wavelength. The disk emerges at 17\( \mu \)m and dominates the \( \lambda \geq 100 \mu \)m images. The finite beam size and dynamic range of any given telescope could result in an apparent size decrease between 10 \( \mu \)m and 100 \( \mu \)m in this case. Such an effect has indeed been discovered in the Haebes MWC 137, whose observed size decreases between 50 \( \mu \)m and 100 \( \mu \)m (DiFrancesco et al 1994, 1998). A switch from envelope to disk domination provides a simple explanation for this puzzling behavior. No single dust configuration can explain such a decrease, a conclusion reached already in MIVE and further affirmed by the results of appendix A. DiFrancesco et al (1998) suggest that this behavior might reflect multiple, rather than singular, sources of heating but the results of appendix A show the inadequacy of this conjecture. The region heated by any single source displays an increase of observed size with wavelength, and the superposition of multiple heating sources preserves this behavior. The opposite trend is possible only when the density distribution contains two distinct components, one optically thick, cool and compact, the other optically thin, warmer and more extended.

A similar effect was detected also in the dust-shrouded main-sequence star Vega. Van der Bliek, Prusti & Waters (1994) find that its 60 \( \mu \)m size is 35\′′ ± 5′′, yet 850 \( \mu \)m imaging by Holland et al. (1998) produced a size of only 24×21\′′ ± 3′′. So the dust distribution around Vega, too, could contain both spherical and disk components with the switch from halo- to disk-dominance occurring somewhere between 60 and 850 \( \mu \)m. Indeed, imaging at 1.3mm by Willner et al (2002) reveal the presence of the disk.

The calculation of the disk emission contains two free parameters, involving the temperature and optical depth at the disk edge.
The disk outer radius \( R_d \) determines its lowest temperature \( T_d \) and a corresponding Planck-peak wavelength. While shorter wavelengths are emitted from a range of disk radii, all longer wavelengths originate from the edge of the disk. The resulting effect can be seen in figure 8, which shows two representative values of \( T_d \). By the model assumptions the disk must be optically thick at the local Planck-peak wavelength everywhere, \( \sim 350 \mu m \) at \( T_d = 25 \) K. As long as the disk edge remains optically thick also at longer wavelengths, the emission follows the Rayleigh-Jeans profile \( f_{\nu,\text{disk}} \propto \nu^2 \). Once the disk edge becomes optically thin, the SED switches to the steeper decline \( f_{\nu,\text{disk}} \propto \nu^2 \sigma_\nu \) at longer wavelengths. The break in the disk SED is controlled by the optical depth of the disk edge, which we specify at 350 \( \mu m \). Figure 9 shows also the effects of varying \( \tau_{350} \) from its smallest value \( \tau_{350} \sim 1 \) to a value sufficiently large that the edge is optically thick at all the displayed wavelengths.

3.2.1 The disk inner radius

The bottom panel of each model in figure 8 shows the variation of the overall SED with viewing angle \( i \). The entire variation comes from the mixing factor \( \rho \) (see equations 20 and 21). Since the parameters \( x \) and \( i \) enter only in the product \( x \cos i \) but not separately, the SED is subject to a degeneracy: systems viewed at different inclination angles will have the same SED if they have the same \( x \cos i \) in addition to all other properties. Because of the rapid decline with distance of the radiation absorbed from the star (cf eq. 17), the disk luminosity, i.e., \( x \), has a steep dependence on its inner radius \( R_{in} \); moving the disk inner edge from \( R_* \) to only \( 2R_* \) removes 56% of the stellar luminosity intercepted by the disk, \( 3R_* \), results in a 72% removal. Such central holes reduce \( x \) but do not impact any other relevant property because they remove only the hottest disk material whose contribution to the overall flux is negligible in comparison with the stellar component.

Figure 9 plots contours in the \( i-R_{in} \) plane of constant mixing factor \( \rho \). It shows, for example, that the SEDs presented in figure 6 for \( i = 70^\circ \) would be the same for systems viewed at \( i = 35^\circ \) if the disk inner radius is increased from \( 1R_* \) to \( 2.2R_* \) in the \( \tau_{\nu} = 0.1 \) case and \( 6R_* \) for \( \tau_{\nu} = 1 \). Although the sizes of these holes cannot be determined from SED modeling of single stars, from statistical arguments MIVE conclude that their existence is essential to produce a plausible distribution of inclination angles.

3.2.2 Flared disks without halos

Thanks to the CG layer–halo equivalence, each model presented here describes also a disk with no halo and with the flaring angle defined by eq. 5 from \( \eta \) and \( \tau_{\nu} \). In particular, the SED presented for \( \eta \sim 1/\nu^2 \) halos describe also flared disks without halo and with \( \alpha \sim 1/\nu \), those with \( \eta \sim 1/\nu \) cover flared disks with constant grazing angle \( \alpha (\beta \sim \ln \alpha) \). The equivalence strictly holds only for disks and halos of the same size. However, the models presented would be little affected if each halo was truncated at \( R_d \) because that would only remove halo emission at long wavelengths where the SED is dominated by the disk anyhow. Since the flaring angle of each equivalent disk reaches \( 2\tau_{\nu} \) at its outer edge, halos whose optical depths require excessive flaring cannot be realized with disks only. This was the problem recognized by Stapelfeldt et al (2003) and Kikuchi et al (2002).

The equivalence holds only for the SED. High-resolution observations would produce widely different images for each halo and its equivalent flared disk, except when the latter is viewed face-on.
4 DISCUSSION

The results of Stapelfeldt et al. (2003) show that every disk imbedded in a halo with $\tau_\nu \lesssim \frac{1}{4}$ can be replaced by a flared disk without a halo and with an identical flux. This mathematical degeneracy explains the success of SED modeling with disk alone a system like GM Aur (Chiang & Goldreich 1999) even though the halo was subsequently discovered in imaging observations (Schneider et al 2003). It also explains why such modeling runs into difficulties and requires excessive flaring when the halos have larger $\tau_\nu$, as is the case in HV Tau C (Stapelfeldt et al 2003) and flat-spectrum TTS in general (Kikuchi et al 2002).

Disks generally do not exist in pure vacuum. Equation [2] defines the circumstances under which the surrounding dust becomes the dominant component of the IR flux. Even at smaller $\tau_\nu$, when not dominating the overall flux, the halo can still dominate the disk heating and make a strong impact on its temperature profile (§3.1). Ignoring the surrounding material can produce misleading results regarding the disk properties, such as its flaring profile.

In spite of the attractiveness of the flared disk as a simple, physical model without any additional components, imaging observations give irrefutable evidence for the existence of extended halos in pre main-sequence stars. The origin of these halos has not been studied yet. Stapelfeldt et al (2003) suggest that a replenishment process, either continued infall from the surrounding ISM or a process, either continued infall from the surrounding ISM or a

REFERENCES

APPENDIX A: OPTICALLY THIN DUST

Consider a cloud heated from inside by a star of radius $R_*$ and effective temperature $T_\star$ (figure [A1]). The star clears out a dust-free cavity of radius $R_c$, determined by dust sublimation $T(R_c) = T_\star$. When the dust is optically thin, the cavity radius can be found from

\[
\frac{R_c}{R_*} = \frac{1}{2} \left( \frac{\dot{\sigma}(T_\star)}{\dot{\sigma}(T_\star)} \right)^{1/2} \left( \frac{T_\star}{T_c} \right)^2
\]
where $\bar{\sigma}(T)$ is the Planck average at temperature $T$ of the absorption cross section $\sigma_{\nu}$ (IE). With standard interstellar dust and $T_\star = 1500$ K, the cavity radius obeys $R_c/R_\star \simeq 100$ at a typical Haebes temperature $T_\star = 10,000$ K. In TTS, on the other hand, the dust is much closer to the star: $R_c/R_\star$ is only 15 at $T_\star = 5,000$ K and as small as 3 at $T_\star = 3,000$ K. The intensity at frequency $\nu$ and impact parameter $b$ (fig. A1) is

$$I_b(\nu) = \sigma_{\nu} \int [(1 - \varpi_{\nu})B_{\nu} + \varpi_{\nu}J_{\nu}] n_d \, dz,$$  \hspace{2cm} (A2)

assuming isotropic scattering. Here $n_d$ is the dust density, $z$ is distance along the path to the observer, $\varpi_{\nu}$ is the albedo at frequency $\nu$, and $J_{\nu} = \int L_{\nu} \, d\Omega/4\pi$. This expression neglects self-absorption by the dust; the error in this approximation is of order $1 - \exp (-\sigma_{\nu} n_d \, dz)$.

### A1 Scattering Wavelengths

Since the dust temperature cannot exceed the sublimation temperature $T_s$, there is no dust emission at $\lambda \lesssim 4\mu m \times (1000 K/T_s)$, only scattering. Diffuse radiation and attenuation between the star and the scattering point can be neglected since our discussion is centered on optically thin dust. Then the only source of scattering is the stellar radiation with energy density $J_{\nu} = L_{\nu}/4\pi r^2$, where $L_{\nu}$ is the stellar luminosity at frequency $\nu$. From equation A2 the scattered brightness is

$$I_{\nu}(\theta) = \frac{L_{\nu}}{4\pi} \varpi_{\nu} \sigma_{\nu} \int \frac{n_d \, dz}{r^2},$$  \hspace{2cm} (A3)

where $\theta = b/D$ and $D$ is the distance to the observer. Since the frequency- and geometry-dependence separate out, all scattering wavelengths share a common image. Only the brightness level varies with $\nu$, and because of the wavelength dependence of $\varpi_{\nu}$, the observed size generally decreases with wavelength when traced to the same brightness level. In any geometry the scattering image always traces directly the variation of column density along the line of sight, the dust temperature profile is irrelevant.

### A2 Emission Wavelengths

At wavelengths longer than $\sim 3 \mu m$, $\varpi_{\nu} < 10^{-2}$ and scattering can be neglected. The Planckian enters in equation A2 as a function of $T$ at fixed $\nu$, which can be well approximated by its Rayleigh-Jeans limit at $T \geq T_s = 0.56/h\nu/k$ and a sharp cutoff at $T_s$. With this approximation the integration is limited to locations along the path where $T \geq T_s$; regions with $T < T_s$ are too cool to emit appreciably at frequency $\nu$. Excluding highly patchy geometries, the highest temperature on the path occurs at $r = b$ (i.e., $z = 0$), the closest distance to the star, and only paths with $T(b) > T_s$ contribute to the brightness. As $z$ increases in either direction, $T$ decreases. The integration is truncated either because the temperature becomes too low, in which case the emission is temperature bounded, or because the edge of the source is reached and the emission is matter bounded. Denote the resulting integration limits $Z_i$ ($i = 1, 2$), then

$$I_{\nu}(\theta) = \frac{2}{\pi} \nu^2 \sigma_{\nu} \int_{Z_i}^{Z_2} kT n_d \, dz.$$  \hspace{2cm} (A4)

In the matter bounded case $Z_i$ is the edge of the source, the integral is independent of $\nu$ and the frequency dependence of the intensity follows $\nu^2 \sigma_{\nu}$. In the case of temperature bounded emission the integration limits introduce additional $\nu$-dependencies that modify this behavior. However, the integration can be extended to $\infty$ whenever (1) $Z_i \gg b$ and (2) the product $n_d T$ of dust density and temperature declines along the path faster than $1/z^2$. Therefore, when these two conditions are met, the frequency variation of optically thin emission is $I_{\nu} \propto \nu^2 \sigma_{\nu}$ even when it is temperature bounded. Independent of geometry, all frequencies that obey these conditions produce a common image, similar to the scattering case; only the scale of brightness varies with $\nu$. This result makes it possible to determine the wavelength dependence of the dust cross section directly from imaging observations.

Similar to the variation along the line of sight, when $b$ increases (moving away from the star) the emission again is truncated by either the matter or temperature distribution. Denote by $T_{out}$ the temperature at the source outer edge. The corresponding emission cutoff wavelength is

$$\lambda_{out} = 100 \mu m \times \frac{40 K}{T_{out}}.$$  \hspace{2cm} (A5)

When $\lambda > \lambda_{out}$, the dust is sufficiently warm everywhere that the emission is truncated only by the matter distribution. The observed size is then $\Theta$, the angular displacement of the source edge from the star, the same for all wavelengths. However, when $\lambda < \lambda_{out}$ the brightness is truncated when $T(b) \leq T_s$ before the edge of the source is reached, resulting in a wavelength-dependent angular size $\theta_s < \Theta$. The observed size of optically thin emission increases with wavelength so long as $\lambda < \lambda_{out}$, the opposite of the trend at scattering wavelengths.

The frequency variation of the dust cross section is well described by $\sigma_{\nu} \propto \nu^n$ with $n = 1–2$. Then to a good degree of approximation, the temperature variation of optically thin dust is $T \propto 1/r^t$, where $t = 2/(4 + n)$, producing the wavelength-dependent observed angular size

$$\theta_\lambda = \Theta \times \begin{cases} (\frac{\lambda}{\lambda_{out}})^{1/t} & \lambda < \lambda_{out} \\ 1 & \lambda \geq \lambda_{out} \end{cases}$$  \hspace{2cm} (A6)

Since $t < \frac{1}{2}$, $\theta_\lambda$ increases faster than $\lambda^2$, a fairly steep rise.
A3 Flux—the SED

The flux can be obtained from equation (A3) by integration over the observed area. At emission wavelengths, the flux at distance \( D \) is

\[
F_\nu = \frac{\sigma_T}{D^2} \int B_\nu(T) \, n_\Delta \, dV.
\]

(A7)

Since the temperature profile of optically thin dust depends only on distance from the star, the dependence on the source geometry enters only from \( n_\Delta \).

As before, the integration is truncated by either the temperature or the matter distribution. Whenever \( \lambda > \lambda_{\text{out}} \), the SED changes from the matter dominated regime. Therefore, the SED changes from \( F_\nu \propto \nu^2 \sigma_T \) at \( \lambda > \lambda_{\text{out}} \) to a flatter slope at \( \lambda < \lambda_{\text{out}} \).

The break in the slope at \( \lambda_{\text{out}} \) can be used to determine the surface temperature \( T_{\text{out}} \). Flux spectral variation shallower than \( \nu^3 \) is a clear indication of temperature-bounded emission and should be accompanied by an image size that increases with wavelength.

A4 Spherical Geometry

Some explicit results are easily derived in the case of spherical symmetry. Thanks to the scaling properties of dust radiative transfer (IE), only two properties are required to specify the geometry. The first is the radial optical depth at one wavelength, say \( \tau_\nu = \sigma_T \int n_\Delta dr \) where \( \sigma_T \) is the cross-section at visual; at every other wavelength, \( \tau_\nu = q_\nu \tau_\nu \) where \( q_\nu = \sigma_T / \sigma_\nu \). The second is the dimensionless, normalized profile of the dust density distribution

\[
\eta(y) = \frac{n_\Delta(y)}{\int_1 n_\Delta \, dy} \quad \text{(A8)}
\]

where \( y = r/R_s \); note that \( \int \eta \, dy = 1 \). Explicit results follow immediately for all power-law density profiles where

\[
\eta = \frac{N}{y^p} \quad N = \begin{cases} \frac{(p-1)/(1 - Y^{1-p})}{(\ln Y)^{-1}} & p \neq 1 \\ p = 1 \end{cases}
\]

(A9)

The shell extends to the outer radius \( Y R_s \), subtending the angular region \( \theta_s \leq \theta \leq \Theta \), where \( \theta_s = R_s/D \) and \( \Theta = Y \theta_s \). At scattering wavelengths

\[
I_{\nu,scat}(\theta) = \frac{N}{2\pi \tau_\nu L_\nu \sigma_T q_\nu} \left( \frac{\theta}{\theta_s} \right)^{p+1} \times \int_0^{\sqrt{(\theta/\theta_s)^2-1}} \frac{du}{(1 + u^2)^{(p+2)/2}}
\]

(A10)

Whenever \( \theta \ll \Theta \) the integration can be extended to \( \infty \), yielding \( I(\theta) \propto 1/\theta^{p+1} \); the brightness decreases as a power law so long as the observation direction is not too close to the halo edge. At emission wavelengths, on the other hand,
