## INFORMATION TO USERS

The most advanced technology has been used to photograph and reproduce this manuscript from the microfilm master. UMI films the original text directly from the copy submitted. Thus, some dissertation copies are in typewriter face, while others may be from a computer printer.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyrighted material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps. Each oversize page is available as one exposure on a standard 35 mm slide or as a $17^{\prime \prime} \times 23^{\prime \prime}$ black and white photographic print for an additional charge.

Photographs included in the original manuscript have been reproduced xerographically in this copy. 35 mm slides or $6^{\prime \prime} \times 9^{\prime \prime}$ black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

The effects of air and lip-pressure variations on the motion of a clarinet reed within an artificial embouchure

The writer would like to express his sincere thanks to many individuals who contributed advice and encouragement throughout the preparation of this dissertation. In particular, I wish to thank Dr. James W. Sherbon for his patience, encouragement, and guidance. I also wish to thank my committee members; Professors Lois V. Edinger, Barbara B. Bair, and Patricia E. Sink for their helpful suggestions. I am especially indebted to Dr. Robert C. Nicklin, Department of Physics, Appalachian State University, for the use of his versatile "Apple-Swiss" computer program and his sympathetic understanding of the nature of this study. I am sincerely grateful to Dr. Walter L. Wehner for his encouragement to pursue the study and for humanistic insights he shared with me along the way. Sincere appreciation is extended to my brother Sid for his engineering expertise and advice.

I wish to express my deep gratitude to my family; Sadie, Frances, Howard, Ann, and Sid for their patience and understanding. Their love and encouragement has undoubtably made the greatest contribution toward the completion of this study. Finally, I wish to thank my wife Elizabeth whose love and patience has sustained me through these many weeks of research.

MILLER, DOUGLAS EVAN, Ed.D. The Effects of Air and Lip-Pressure Variations on the Motion of A Clarinet Reed Within An Artificial Embouchure. (1988) Directed by Dr. James Sherbon. 226 pp .

To observe the influence of air and lip-pressure variations on reed motion, a blowing chamber containing an artificial"embouchure device was constructed into which a clarinet was inserted and sealed at the barrel joint. A DC light source was directed through the bell end of the clarinet into a photo transistor mounted near the mouthpiece. Light fluctuations produced by the reed's movement were converted to voltages and directed to an analog-to-digital converter unit interfaced with an Apple IIe computer.

In air-pressure experiments, lip pressure was held constant while air pressure was varied. In lip-pressure experiments, air pressure was held constant while lip pressure was varied. Intensities were measured on a sound-level meter and air-pressure was monitored via a U-tube water manometer connected to the chamber; thus, the reed's vibrational patterns were observed at specific air pressures, lip pressures, and itensities.

Conclusions: l) For low-intensity tones in all registers, reed motion was sinusoidal. 2) For high-intensity tones in all registers, the reed closed for a portion of its cycle and smaller vibrations were superimposed upon the reed's waveform when it reached maximum displacement. 3) The reed's mode of vibration in
the steady state matched closely the mode of the air column. 4) The reed's natural frequency of vibration was distinguishable within the steady state waveform. 5) Small inaudikle vibrations of the reed at its natural frequency were evident before the reed began to follow the requirements of the air column. 6) At constant lip pressure, an increase in air pressure increased reed amplitude and closure time but did not affect the reed's frequency of vibration. 7) At constant air pressure, lip-pressure reduction increased reed amplitude and intensity. 8) At specific air and lip pressures conducive to a wide range of intensities, closure was not more than 48 percent of a cycle. 9) An increase in reed amplitude did not always produce an increase in intensity level.

## CHAPTER I

INTRODUCTION

The oscillations of a reed are paramount for the production of sound on a clarinet. Not only is it the most unstable and inconsistent part of the instrument, but also the basic element providing the physical vibration necessary for the production of tone. For these reasons, the reed is frequently the center of attertion when tone quality is less than satisfactory. Because most clarinetists lack a scientific understanding of the characteristics surrounding a reed's vibrational patterns, there is justification for seeking empirical data which will serve as a basis for establishing foundations leading toward better control of the reed.

## Purpose of the Study

The purpose of this study was to observe the influence of air and lip-pressure variations upon the oscillatory patterns of a clarinet reed as it vibrated at different frequencies. Results from the study may yield objective data about reed motion which can be of substantial significance in pedagogical applications regarding control of lip and air pressures necessary for optimum tonal
production. Furthermore, the observed changes in the oscillatory patterns of the reed may have an effect on the shape and size of the puffs of air entering the body of the clarinet; consequently, results may indicate that vibrational patterns of the reed may produce harmonic variations in the tone. This potential might explain tonal differences observed when two clarinetists perform on the same instrument.

## Delimitations of the Study

This study is not meant to be conclusive, but rather, exploratory. In the interest of conducting a comprehensive examination of the effects of air and lip-pressure variations on reed motion, the investigation necessarily encompassed specific physical characteristics of reed motion such as intensity, amplitude, and closure. A primary motive in conducting this study was to supplement previous findings regarding reed motion by considering the effects of air and lip-pressure variations, variables which have been unheeded in previous studies of this nature. Conclusions from the study are divergent in the interest of presenting a multilateral theory of reed motion under the two conditions stated above. The efficacy and statistical sophistication of the findings are therefore somewhat limited in the interest of this divergency.

## Significance of the Study

Single-reed instruments have been common since antiquity. Although manifesting a variety of physical forms, acoustical principles underlying primitive and modern single-reed instruments are very similar. They are comprised of an excitation mechanism, or tone-producing element, coupled to the body of the instrument, which, in turn, shapes an internal air column according to its contour. In a clarinet, the air column is in the shape of a cylinder. The excitation system, consisting of the embouchure, reed, mouthpiece, and ligature, transduces air-pressure provided by the performer into regular air puffs, thus exciting the air column, which, in turn, reacts to vibrational patterns of the reed. The excitation system must therefore match the acoustical requirements of the cylinder (bore) to which it is attached. Stubbins (1965) stated that "intonation, tone quality, ease of performance, flexibility, articulation, and dynamic control, are all affected by this reactance between the air column of the instrument and the tone-generating system" (p. 60).

Historically, a great variety of methods have been employed to excite the resonance frequencies of the air column. The "shepherd's pipe," one of the most primitive single-reed instruments, had a reed which was simply a sliver of cane split from the body of the instrument; thus,
a single tube of cane formed the mouthpiece, ligature, and reed. In the seventeenth century, when this sliver was separated and bound to the instrument by a string, it was given the name "chalumeau." Other single-reed instruments, like the "pibgorn," or "Welsh hornpipe" (sixteenth century), had a reed which was completely enclosed within a chamber and did not make direct contact with the performer's lips. The modern clarinet is a descendant of the chalumeau since it has a separate reed attached to the exterior of the instrument.

Since the creation of the clarinet by Johann Denner in the seventeenth century, trial and error on the part of craftsmen and musicians has yielded improvements upon its various parts. The physical weight of the key system, for example, has increased dramatically, requiring it to be mounted to a body of greater density and strength. Other improvements include a more efficient placement of tone holes, providing instruments with better intonation, and alterations on the size of the bore for greater tonal projection and ease of playing. In contrast, the design of the mouthpiece and reed has varied sonsiderably less than the lower sections of the instrument described above. The reed remains today, as it was in Denner's time; a major variable of tone production over which the clarinetist has immediate and direct control. The mouthpiece, barrel, and lower clarinet sections are not economically feasible items
to replace while the reed is generally considered to be easily obtained, altered, and adjusted. For this reason, once a player has settled on a specific configuration for the instrument, attention is focused on the reed when tone quality is less than satisfactory. Not only is the reed the most inconsistent variable of clarinet tone production but also the part which embodies the most motion. The physical behaviors of vibrating reeds are therefore important for an understanding of the acoustics of the instrument and control of the sound which is produced. Assuming the excitation mechanism forms a carefully balanced system consisting of the mouthpiece, embouchure, ligature, and reed, it follows that this system may be mathematically described as a complex equation comprised of these four variables. If response of the system is less than satisfactory, the equation may be rebalanced through regulation of the variables. Since these variables can be manipulated by the performer to balance their relationship within the system, it becomes evident that specific parameters governing the effects each variable has upon the equation might be formulated. Alterations in any of the four variables (excluding the human factor), may result in profound alterations of the entire system. Since the mouthpiece and ligature are manufactured as part of the instrument, they are generally purchased as a package; thus the reed and embouchure often become logical points of
adjustment. In practice, some techniques of reed adjustment appear to be more effective than others; thus, one assumption forming a basis for the present study lies with an inconsistency in method sustained by a general lack of knowledge about single-reed behavior.

## Theories of Reed Motion

Theories regarding the function of the single reed within the excitation mechanism can be traced back to the 1930 s and divided into two distinct categories. One group of theories was based upon the premise that the reed never completely closed the chink or aperture between the reed and the mouthpiece. Ghosh (1938) developed a mathematical theory of reed motion based upon this premise. A similar view of non-closure was presented by Redfield (1934) in his study of air-column behavior in orchestral wind instruments. These theories, however, were not supported by experiments conducted by McGinnis and Gallagher (1941); consequently, a second theoretical category emerged. Using photographs of reed motion produced under a strobe light, McGinnis and Gallagher concluded that the reed completely closed on the mouthpiece during part of a vibrational cycle. Since then, theories have been presented which align more closely with these findings (presented in Chapter II).

The McGinnis and Gallagher (1941) study constitutes a major contribution to the literature on reed motion and very few subsequent studies in this area have been published. Their research greatly expanded knowledge about the vibrational cycle and behavior of the reed. Although the McGinnis and Gallagher study was an important contribution to research on reed motion, numerous variables possibly affecting their findings were left uncontrolled. Specific intensities, lip pressures, and air pressures, for example, were not taken into consideration in their research. Further studies in this area were not conducted until approximately two decades later when John Backus (1960) published observations of ocilloscopic traces of light variations passing between the reed and mouthpiece as tones were produced. As in the McGinnis and Gallagher study, specific parameters of his experiments were not published. These studies, although important in their own right, left many questions unanswered regarding reed behavior under more specifically controlled conditions and did not address the critical interrelationship between air pressure, lip pressure, and reed motion. Research, as exemplified in the present study, may reveal the importance of careful adjustment of air and lip pressure and yield parameters regarding their interaction in the production of musical sound.

## Reed Motion and Tone Quality

Vibrational patterns produced by the reed may have an important bearing upon clarinet tone quality. Since applied lip and air pressure are not consistent between players, control of these two factors may demonstrate that reed vibrations are important in the quality of tone produced. Previous research (Parker, 1947; Lanier, 1960; Backus, $1961,1963,1964$ ) has shown that the material from which the body of the clarinet is made has little effect upon its tone quality. The tonal spectrum which is produced might therefore depend largely upon variables within the excitation mechanism. In addition, studies of the excitation mechanism by Parker (1947) and Mooney (1968) have suggested that the size and shape of the oral cavity does not affect tone quality; thus, evidence supports the isolation of other variables within the excitation mechanism affecting tone quality such as air pressure, lip pressure exerted by the embouchure, amount of mouthpiece inserted within the embouchure, ligature pressure, reed mass, reed density, and the internal and external dimensions of the mouthpiece. By controlling all of these variables except air and lip pressure, the effects of air and lip-pressure variations upon the vibrational pattern of the reed may be observed. If the wave form produced by the reed changes in each register for different air and lip
pressures, it might be concluded that air is entering the air column in varying amounts and configurations. Therefore, the size and shape of the air puffs entering the clarinet may depend upon vibrational characteristics of the tone being produced. This would indicate that the reed's vibrational pattern could be considered as a possible factor contributing to the harmonic structure of the tone.

## Statement of the Problem

With the growth of public school instrumental music during this century, a practical interest in the technical aspects of tone production in wind instruments has been fostered among teachers and researchers. Studies of reed motion have been conducted in an attempt to better understand the often curious behavior of woodwind instruments. In recent years, researchers have presented many intriguing questions regarding reed motion, and with the current availability of computer analysis of the tonal spectrum, the possibility of scientific, innovative, and exacting research in this area has become feasible.

Basic characteristics of reed behavior have not, to date, been studied in a thorough and organized way. Research has been, at best, general, and sometimes, misleading. Interesting theories regarding reed motion have surfaced regularly, but few have been supported by quantitative data. To understand reed motion to a degree
necessary for making accurate generalizations about its behavior requires systematic research conducted under carefully controlled conditions. Such research might form a substantial foundation for more diverse theories of reed motion.

To date, few studies of reed motion have been conducted under circumstances which invited accurate control of the variables previously mentioned as being possible contributors to tone production on the clarinet. As a result, many methods used to physically control the action of a reed are obvious products of trial, error, and inefficient ways of measuring. Physics of woodwind sound production are generally dependent upon physical characteristics of reeds and their motion under specific conditions. Benade (1960) wrote:

The makers of wood winds not only discovered the ideal shapes generations ago; they have also empirically exploited the effect of departures from the ideal. They judiciously alter the cross section of the bore by a few thousandths of an inch to compensate for various upsetting effects caused by the complex behaviors of reeds and holes. . . . Although the necessary modifications of a bore can in general be predicted quantitatively by proper mathematical analysis, to my knowledge such methods have almost never been employed by the manufacturers of wood winds. They make the final adjustments in the taper of each bore by a process of trial and error (p. 150).

Detailed computer analyses of the vibrational cycle of the reed are needed to explain its motion in a more exact and scientific manner. A thorough understanding of reed behavior may enhance existing knowledge regarding the
acoustics of the clarinet and its pedagogy.
A primary objective of this study was to control variables of the excitation mechanism which might affect reed motion. In this way, it was hoped that the study would clearly interrelate specific aspects of air and lip-pressure variations on reed motion and yield practical theories which might serve as a foundation for further research. A second objective was to use the findings to clarify existing theories of reed motion which might better serve the demands of current pedagogical practice. For example, in consideration of research conclusions and subsequent observations presented above, two questions emerge as significant points of concern: if the reed does not completely close upon the mouthpiece, regardless of the amount of applied air pressure, it might be concluded that maintaining a perfectly flat surface on the back of the reed is not necessary; conversely, if the reed does close completely for some tones, then a flat reed surface would appear to be imperative.

## Foundations for the Study

The following assumptions are presented in regard to this study: (1) via the aid of instrumentation, the reed will exhibit observable motion when a sound is produced, (2) controlled variations in air pressure will be externally and artificially applied to the clarinet at the
mouthpiece end in a manner judged to be similar to human performance, (3) "intensity" will represent sound pressure level, (4) controlled variations in air pressure will produce variations in the intensity level of the sound produced by the clarinet, (5) the natural vibrational frequency of the reed will be damped by an artificial lip mechanism, (6) threshold sound pressure will be the air pressure needed to produce an audible sound, and (7) "pitch" [the psychological counterpart of frequency which is the number of physical vibrations (oscillations) of a mass per second] will represent tones produced by the clarinet.

Primary research questions which formed the foundation
for this study are listed below.

1. At specific frequencies, air pressures, and lip pressures, does the reed completely close on the mouthpiece during any part of its cycle of vibration?
2. What is the interrelationship between applied air pressure, lip pressure, reed amplitude and intensity at specific frequencies?
3. What is the relationship between the frequency of the reed's vibration and the fundamental frequency of the tone produced?

Secondary research questions of focus within this study are as follows:

1. Do air-pressure requirements for low-intensity tones vary with applied lip pressures?
2. What parameters of lip and air pressure are necessary when changing intensity levels on the clarinet?
3. How do air-pressure requirements vary with the frequency being produced at a specific intensity level?
4. What behavior does the reed exhibit at air pressures which are below the threshold of sound production?

## CHAPTER II

## REVIEW OF THE LITERATURE

The earliest attempts to explain reed motion on the clarinet were in the form of mathematical procedures based upon the assumption that during the vibrational cycle, the reed only partially closed the aperture between the mouthpiece and the reed. These theoretical explanations of the action of the vibrating reed were an attempt to clarify the presence of even-numbered harmonics in the clarinet tone which had first been observed by Blaikley (1884) and Miller (1926). Prior to these discoveries, the clarinet was generally considered to behave as a closed tube (stopped tube) with its audible tone containing only odd-numbered harmonics.

Das (1931) deduced mathematically that the periodicity of the reed's vibration on a mouthpiece relied upon the length of the tube to which it was attached, thus vibrating at the fundamental frequency of the tone being played. He concluded that the motion of the reed could be described as vibration around an equilibrium position and that the reed moved periodically toward and away from the mouthpiece, completely closing the reed-mouthpiece aperture during the part of the cycle when the air pressure within the mouthpiece was low. Das (1931) stated:

The solution . . . can be interpreted as a vibration about a centre of rest which has a sudden shift. . . alternately away from and towards the mouth-piece . . . thus during a condensation the reed opens the chink fully so as to admit air into the tube and shuts up during a rarefaction. . . . The reed vibrates practically in the same phase with the change in pressure in the mouth-piece [sic], opening itself so as to admit air into the tube when the pressure is large and shutting up at low pressure" (p. 231).

Das (1931) deduced that when air pressure within the mouthpiece was low, the reed was drawn inward against its surface (lay). Since, in this case, more of the reed's back was in contact with the surface of the mouthpiece, the vibrating length of the reed was shortened. When air pressure within the instrument equalized with air pressure in the mouth, the reed returned to the position of rest, leaving less of the reed's back against the lay of the mouthpiece and more of the reed's length free to vibrate. In opposition to Das, Redfield (1934) concluded that the reed never completely stopped the applied air supply entering the body of the instrument from the performer's mouth. Using a stethoscope, Redfield observed that sounds transmitted to the medium from the instrument were also transmitted to air confined within the buccal, pharyngeal, laryngeal and pulmonary cavities of the player's body. He concluded that if the reed were closing completely on the mouthpiece, these frequencies would not have been observable within the neck of the player.

A mathematical theory was presented under the same assumption by Ghosh (1938) in which he deduced, at
unspecified frequencies, that the blowing pressure within the mouth remained constant while the pressure within the clarinet and across the reed showed periodic variations. These periodic variations, according to Ghosh, were the result of only a partial closing of the reed on the mouthpiece. He writes: "the chink between the mouthpiece and the reed never shuts completely, that is, the conductivity of the chink is not zero, as in the older theory" (p. 262).

An experimental attempt to "freeze" the image of the vibrating reed was conducted in Germany by Ashoff (1936) using an artificial embouchure and a stroboscope. In order for the reed to be properly photographed, however, he found it necessary to cover the reed with an aluminum coating. This may have caused the reed to exhibit artificial behavior during its vibrational cycle. Ashoff concluded that the reed did not completely close on the mouthpiece during its cycle of vibration.

An experimental study similar to Aschoff's was completed by McGinnis and Gallagher (1941) whereby an artificial embouchure was used, in conjunction with a stroboscope, to produce stop-action photographs of the reed as it vibrated. Unlike the Aschoff study, McGinnis and Gallagher were able to successfully photograph the reed without covering it with aluminum. For tones of high intensity, McGinnis and Gallagher (1941) used photography
to support the premise that the reed remained closed for about $1 / 2$ of its cycle, spent $1 / 4$ of the cycle in transit, and opened for the remaining $1 / 4$ of the cycle, regardless of the frequency of the tone being played. For any pitch, the fundamental frequency of the reed's vibration was found to be stable within one percent of the fundamental
frequency of the tone produced. The researchers found that under normal conditions, the reed vibrated as a unit with the extreme tip remaining parallel to the facing of the mouthpiece. Regarding the motion of the reed for tones of high intensity, they stated:

The motion of the reed during a complete cycle is of interest. Consider that the chink is just on the point of closing. With the aperture closed, the reed appears motionless to the eye for about half the time of a complete cycle. It then leaves the mouthpiece with relatively high velocity and reaches its position of maximum displacement in a series of short spurts. The time spent apparently motionless at maximum displacement is roughly a quarter of the fundamental period. The tip of the reed now returns to the mouthpiece in another series of short spurts, and the fundamental cycle is complete. Thus the actual motion of the reed occupies only about a quarter of the entire period. This description agrees in a general way with the results predicted by Das (1931) in his mathematical development, which, however, were without experimental confirmation (p. 531).

To determine if the reed closed on the mouthpiece,
Obrien (1953) allowed an adjustable needle to protrude through the aperture between the reed and mouthpiece. He found that when the clarinet was blown in a "normal" way, a tone was produced only when the needle was drawn below the plane of the mouthpiece surface. He concluded from these
results that the reed must close completely in order for a sound to be produced.

Using an artificial embouchure, John Backus (1960 to 1974) at the University of Southern California, Los Angeles, conducted a distinguished and inventive series of investigations on the vibrations of clarinet reeds. In one study, Backus (1960) directed light through the bell end of a clarinet and into the aperture between the reed and mouthpiece, where fluctuations in light intensity were monitored by a photomultiplier tube (a light-sensitive transducer) mounted at the tip of the mouthpiece. As the artificially-blown reed vibrated, light-intensity variations were observed on an oscilloscope. By superimposing photographs of oscilloscopic wave patterns created during various stages of the reed's vibration, comparisons were made between the reed's closure times. Backus concluded that the motion of the reed was quite simple and had nearly the same pattern for all tones throughout the range of the clarinet. For high-intensity tones in the chalumeau register, it was observed that the aperture between the reed and the mouthpiece closed for nearly one-half of the cycle, opened for almost one-half of the cycle, and spent the short remainder of time in transit. For low-intensity tones, he found that the aperture did not close completely and the motion became nearly sinusoidal.

Backus (1961) used an artificial embouchure to study the relationship of reed motion to air-column vibrations. A small condenser microphone was inserted within the mouthpiece and arranged so that the microphone assembly could be used in conjunction with the photocell assembly mentioned above. The signal outputs from both assemblies were directed to an oscillosope, making possible simultaneous observation of reed and air-column vibrations. Backus concluded that variations in reed motion followed closely the variations in the air column, thus adding more support to the theories of Das (1931).

In an experimental study of effects of reed/mouthpiece aperture on minimum blowing pressures in the clarinet, Backus (1962) used an artificial embouchure to measure reed/mouthiece aperture, blowing pressure, and operating frequency when the clarinet was "barely" sounding. He found that minimum blowing pressure was directly proportional to reed/mouthpiece aperture and reed stiffness.

Coppenbarger (1971) investigated a vibrating clarinet reed utilizing an artificial embouchure, high-speed cinematography, and a harmonic wave analyzer. He attempted to correlate tone production with reed movement, thus concluding that the reed vibrated at the same frequency as the frequency of the tone being produced. Coppenbarger observed that the lip pressure required to produce a tone
with an artificial embouchure reduced the mouthpiece-reed gap 43 percent from its rest position, and that the reed closed completely about 40 percent of a cycle, but never more than 45 percent.

## Studies of Reed Closure Times

The earliest observations regarding the reed's closure time on the mouthpiece were made by McGinnis, Hawkins, and Sher (1943). In an experimental study of tone quality of high-intensity tones, they observed that it was the closure time of the reed which caused the clarinet to behave as a "stopped tube," thus producing odd-numbered harmonics. They observed that during one complete cycle of the reed's vibration, the sound disturbance (condensation) had traveled four lengths of the clarinet. Regarding one cycle of vibration, they stated: "It is important to note that the reed is in its closed position for at least half of the entire period" (p. 229).

It was not until 1960 that Backus studied closure times for loud, medium, and soft tones using tones of different frequencies. Backus (1960) stated:

First, it will be noted that for loud tones the reed aperture is completely closed for nearly half the cycle, and practically completely open for the other half. As the intensity decreases the closed time diminishes, and for soft tones the aperture does not
close at all during the cycle. Second, the waveform is fairly complex for loud tones although the fundamental predominates; for soft tones the waveform is nearly sinusoidal. Third, the waveform becomes simpler as the frequency is increased. (p. 808)

It is possible that various closure times may influence the tone quality produced. It may be assumed that the longer the reed stays open, the amount of air that would be admitted into the body of the clarinet would be greater. This would produce a larger and differently shaped puff of air than one which would result from a longer closure time. Backus (1962) observed:

The harmonic structure of the clarinet tone for several different notes of the scale was recorded at four different loudness levels. It was found that the higher harmonics disappeared as the tone became softer, the number of harmonics decreasing from as many as 15 or more for loud tones to 1 or 2 for soft tones. (p. 717)

Stubbins (1965) also stated that different closure times of the reed had a direct influence on tone quality, but did not support his contentions with quantitative data. Stubbins concluded that a vibrating reed, opening and closing on the mouthpiece, behaved as a valve, admitting "air puffs" of different shapes and sizes into the body of the clarinet. These air puffs, Stubbins contended, contained the potiential for different harmonic patterns.in the tone. He stated:

If a valve flies open and shut very abruptly, and admits the air for only about one-twentieth of a cycle of vibration, it has a potential of producing approximately equal amounts of all of the harmonics. If a valve flies open abruptly, and remains open for about one-fourth of a cycle, and then shuts abruptly,
it has the potential of producing a harmonic pattern which is quite different from the former. A valve opening for only one-eighth of a cycle, again produces a different pattern (p. 59).

When Backus (1961) tested different reeds for closure using an artificial embouchure, he concluded from his observations that some reeds were closing the mouthpiece aperture only on one side. He therefore concluded: "the quality of the tone produced by the reed as judged by the ear does not seem to depend on whether or not the aperture closes completely" (p. 808).

Backus (1966) also studied the effect of warping of the reed tip on clarinet tone. He found that the aperture between the reed and mouthpiece does not close completely during the part of the cycle that the reed is in contact with the mouthpiece due to the presence of a certain amount of warping. That part of the reed which is not in contact with the mouthpiece can still oscillate with a small amplitude at a high frequency.

In a study of the effects of wall material on the steady-state tone quality of woodwind instruments, Backus (1964) found that vibrations of the clarinet body felt by the performer when playing are "caused by the reed beating against the mouthpiece, and not to radial vibrations due to expansion of the tube because of the pressure of the internal standing wave" (p.1884).

Coppenbarger (1970) used high-speed motion pictures of the reed to analyze its movement for tones of high
intensity. By counting the number of frames in the high-speed film, Coppenbarger was able to draw interesting conclusions regarding the reed's closure time on the mouthpiece. Although he analyzed tones of unspecified intensities, he observed a rather consistent pattern of reed behavior. He stated:

The reed usually remains closed with the mouthpiece 40 percent to 45 percent of the complete cycle. There are times when the reed just touches the mouthpiece and opens. When the tip of the reed leaves the mouthpiece, it starts to open in the shape of a sine wave but rapidly gains speed, which tends to square up its shape (p. 113).

The studies reviewed above represent a comprehensive overview of research on reed motion to date. They were focused primarily upon theories regarding reed closure and presented, in this writer's opinion, a somewhat simplistic view of reed motion at unspecified lip pressures and intensities. The predominating lack of attention in these studies to the effects of lip and air-pressure variations on reed motion have yielded tentative and somewhat incomplete evaluations of specific aspects of the findings. For example, an irregularity may be observed in the findings, and subsequent evaluation, of McGinnis, Hawkins, and Sher (1943), in which they seem to contend that the clarinet acts as a "closed pipe," producing odd-numbered harmonics, as a consequence of the reed's closure on the mouthpiece. If applied lip and air-pressure variations had been considered in their experiment, or the specific degree
at which the reed may be considered to be "closed" on the mouthpiece, the researchers may have been reluctant to present such a simple and comprehensive statement. A study such as the present one, in which air and lip-pressure variations are considered in relationship to reed motion, is warranted to explain anomalies found in modern theories of reed motion.

## CHAPTER III

PROCEDURES AND EQUIPMENT

## Procedural Overview

The purpose of this study was to observe the vibrations of a clarinet reed in all registers as various air and lip pressures were applied. In an attempt to observe the motion of a clarinet reed during the production of a sound, an air-tight chamber was constructed to serve as an artificial embouchure (see Figure l). Multidirectional manipulation of lower-lip pressure upon the reed was made possible by utilizing an externallycontrolled "lower-lip" mechanism housed within the device. The mouthpiece end of the clarinet was inserted into the chamber and sealed at the barrel by means of a rubber gasket. The clarinet was supported on the outside by an adjustable stand which was designed to allow manipulation of its angle of entry into the embouchure chamber. Air pressure within the chamber was controlled by regulating a potentiometer connected to the motor of an air pump and monitored with a water manometer linked to the chamber.

A variable direct-current (DC) light source was placed opposite the bell of the clarinet and adjusted so as to

Figure 1. The Complete Apparatus
direct light through the length of the clarinet and into a photo transistor. Pitches were produced by removing keys from the instrument and inserting rubber plugs into appropriate holes. The clarinet was made to sound by slowly increasing air pressure and simultaneously adjusting the lower-lip mechanism. Motion of the reed was observed using computer-assisted observation of light-intensity variations received through the mouthpiece/reed aperture. Subsequent effects of air and lip-pressure variations upon the motion of the reed were studied.

Equipment

Specifications of the Artificial Embouchure and Lower-Iip Mechanism

Embouchure Chamber

An air-tight wooden chamber measuring $47 \mathrm{~cm} \times 18.5 \mathrm{~cm}$ x 40.7 cm was constructed of $3 / 4$-inch white pine. Foam insulation was used between all joints to provide an airtight seal. The ends of the chamber consisted of 1/4-inch plexiglass mounted on eight evenly distributed posts of threaded stock which were embedded and glued within the main chassis. Wing nuts, attached to the embedded posts, pressed the plexiglass against an insulating layer of $3 / 4$-inch foam weatherstrip tape and provided an effective seal between the side plates and the
chamber. This arrangement allowed the plexiglass to be easily removed when internal adjustments became necessary.

A hole three inches in diameter was drilled into one side of the chamber and was fitted with a three-inch rubber plug through which a smaller hole was cut to accomodate the barrel of the clarinet. In this way, the clarinet could be separated from the chamber quickly and easily for adjustments. Air was delivered from an air supply via a 1 1/2-inch diameter hose which was attached to the opposite side of the chamber and sealed with clear General Electric Silicone sealer.

Mechanism for Adjusting Pressure and Position of Lip Cushion

Multidirectional manipulation of lower-lip pressure upon the reed was made possible by utilizing an externallycontrolled mechanism housed within the chamber (see Figure 2). Horizontal movement of the lip mechanism was achieved by mounting four $1 / 4$-inch steel rods near the top of the chamber and spacing them in a square formation, each two inches apart. This provided a stable foundation upon which a wooden plate of $3 / 4$-inch pine could slide horizontally through the chamber. External control was achieved by mounting an 8 -inch screw rod parallel to the other steel rods, but connected to the pine plate with a sliding lock washer. The other end of the screw rod passed through a threaded nut secured within the opposite side of the

Figure 2. The Artificial Embouchure and Lower-Lip Mechanism
chamber and fitted with a beveled knob. A washer arrangement at each end of the screw rod allowed it to be turned forward or backward through a nut mounted in the side of the chamber, pushing it in a horizontal motion against the pine plate. This provided an accurate and efficient method of moving the pine plate left or right. The pine plate, in turn, extended into the lower part of the chamber and supported another $1 / 4$-inch steel rod axle for the lip mechanism.

Vertical movement of the lip mechanism was achieved by a "see-saw" arrangement along the axle of the pine plate. A second pine plate supporting two brass strips was attached to the axle of the first pine plate. These brass strips extended beyond the length of the second plate by three inches in each direction. In one direction, they extended to an externally-controlled mechanism which provided vertical movement, while in the other direction, they extended to hold a steel axle supporting the lip mechanism.

The externally-controlled mechanism which provided vertical movement was similar in design to the horizontal mechanism described above. Two steel rods, extended from the top to the bottom of the chamber as sliding posts for a third pine plate. A rod of threaded stock was mounted to the plate and threaded through a nut mounted in the top of the chamber to accomodate a knurled knob. By turning the
knurled knob, the rod and the pine plate could be moved vertically in either direction.

To achieve simultaneous movement in all directions, it was necessary to design the two mechanisms so that one movement did not interfere with the other. By placing the brass extenders from the first plate on top of the second plate, they were free to slide across it in a horizontal direction. At the same time, when the vertical plate was moved, it would lift or lower the brass extenders and provide a "see-saw" action across the other plate. By simultaneously adjusting the two external knobs, multidirectional movement of the brass extenders was possible without interference.

## The Lip Mechanism

The brass extenders supported the lip mechanism which consisted of a $1 / 2$-inch diameter rubber cylinder molded to a $1 / 4$-inch steel axle (see Figure 3 ). The lip cushion was constructed from 1 1/4-inch adhesive-backed foam insulation. The adhesive allowed a l-inch square section of insulation to be wrapped around the rubber cylinder. Rubber bands provided additional security to the insulation. After experimenting with a number of different materials, it was determined, by feel and touch, that this arrangement closely simulated the actual texture of a human lip.

## 

Four separate devices were attached to the floor of the chamber: an adjustable mounting for a Type FPT-100 photo transitor; an atomizer mounted so that when a rubber bulb was squeezed cutside the chamber, moisture was sprayed toward the reed/mouthpiece aperture; a thermometer; and a ruler marked in millimeters mounted parallel to the inserted clarinet. A pointer fastened to the axle of the lip mechanism moved along the ruler in such a way that horizontal movement of the mechanism along the reed's surface could be accurately gauged.

## Air Pressure and Regulation

The air supply consisted of an air pump housed within a sound-reducing box. The box was constructed from pine, measured $45.5 \mathrm{~cm} \times 47.0 \mathrm{~cm} \times 61.0 \mathrm{~cm}$, and was lined internally with 2 -inch thick rubber foam insulation. The speed of the air pump was regulated by a potentiometer. A hose with an inside diameter of 28 mm was used to distribute air to the chamber since both the volume of air and the air pressure have been determined to be important factors in producing a sound on the clarinet (Coppenbarger, 1970). A standard U-tube manometer was used to measure blowing pressures. Mercury is the most commonly employed liquid in manometers because of its low vapor pressure and its high density. This produces a generally negligible contamination of the gases whose pressures are being
measured and permits the use of manometers of convenient dimensions (Reiman, 1971, p. 218). However, after pilot trials, it was determined that water gave a more sensitive measurement, due to its ability to move greater distance under a specific pressure. Consequently, all measurements were made in terms of centimeters of water displaced. As water lowered in one side of the manometer, it would rise in the other. Respective amounts of displacement in each side were noted and summed. Atmospheric pressure was considered a constant and did not enter into the calculations.

## Equipment Used in Quantitative Analyses

Quantitative data were collected using an Apple IIe computer interfaced with a Type FPT-100 photo transistor via a Nalandata A2 Data Converter and a 6522 VIA card installed within the computer. The photo transistor was recessed and mounted within a 6-inch alumninum cylinder having an outside diameter of 1 cm and mounted on a base which permitted accurate alignment with the mouthpiece aperture. A wire from the photo transitor was connected to a nine-volt alkaline battery before it was passed through the wall of the chamber. A 12-volt direct-current light source was placed opposite the bell of the clarinet and adjusted so as to direct the light through the length of the clarinet and into the photo transistor. Power for the
light source was provided by a Model 73 P variable power supply. Direct current versus alternating current (AC) was used to control fluctuations in light intensity which occurred when alternating current was applied. The signal voltage produced by the photo transitor was amplified and directed to an 8-bit analog-to-digital converter interfaced with the computer. The analog-to-digital converter was used in conjunction with "Apple-Swiss" (1986) software (see Appendix A) to produce numeric and graphic representations of the variations in light intensity received by the photo transisitor. For purposes of comparison, a Technics Model RP-3500E Electret Condenser Microphone of 600 ohm impedence was used to record air-pressure variations.

## Data Converter Specifications

The analog-signal output from the photo transitor was fed into an analog-to-digital converter (Nalandata A2A Data Converter) designed by Nicklin (1986) at Appalachian State University. The Nalandata A2A was a small unit placed outside the computer. The line from the photo transistor was connected to an input jack of the Nalandata A2A which fed the signal to a linear amplifier offering switchselectable gains (amplifications) of . $33,1.0,3.3,10,33$, and 100 times the original signal voltage. Gain refers to the amount of amplification applied to the measured voltages. Amplification was used, in some trials, to
increase the vertical aspect of the graphs for clarity. After amplification, the signal was passed to an 8-bit analog-to-digital converter capable of discriminating a maximum of 256 voltage levels with accuracy within 0.4 percent. A Versatile Interface Adapter (VIA board) was plugged into the computer and interfaced the Data Converter to the Apple IIe. Accompanying the Nalandata A2A was a software program designed by Nicklin (1986). Graphs were printed on a Star NX-10 dot-matrix printer using a graphics dump program [ Triple Dump (1984) by Beagle Brothers Micro Software, Inc.].

## Control of the Variables

Vibrational patterns produced by a reed may have an important bearing upon the tone quality which is produced by a clarinet. Since lip pressure and air pressure are different for every player, manipulation of these variables is necessary to demonstrate the possiblility that reed vibrations are an important element in the production of specific tone qualities. Variables within the excitation mechanism which might affect tone quality are: air pressure, lip pressure, ligature tension, reed mass, reed density or stiffness, and the internal and external dimensions of the mouthpiece. By controlling all of these variables while manipulating air and lip pressure, the effects of the latter two variables upon the vibrational
pattern of the reed may be observed.
The following variables were controlled during the experiment: applied air pressure, applied lip pressure; ligature pressure; reed mass; reed density; and dimensions of the mouthpiece. The independent variables were applied air and lip pressures. The dependent variable, which resulted from manipulation of applied air and lip pressure, was the vibrational pattern of the reed as shown by light-intensity variations received by the photo transistor. The artificial embouchure not only made it possible to visually observe the reed's motion but allowed for precise control of the variables. Such control would have been impossible if a human subject had been used.

## Position and Applied Pressure of Lower-lip Mechanism

The pressure exerted by the lower-lip mechanism was kept constant in some of the experimental tests. In others, it was varied, in conjunction with air pressure, to produce a sound on the clarinet as the reed was set into motion by the artificial-embouchure mechanism. Too much pressure exerted by the lower-lip mechanism resulted in a "choked" sound and too little pressure caused familiar "squeaks" or "squeals" that are often heard when beginners play the clarinet. Backus (1961) found that "the frequency of a clarinet tone is influenced to some extent by the lip pressure on the reed, giving the clarinetist some control
over the intonation of the instrument" (p.862). Backus (1961) writes:

The damping provided by the player's lip is important in reducing the tendency to produce high-frequency vibrations. The mass of the reed is an important factor determining the production of higher harmonics and is thus of considerable importance to the quality of the tone produced (p. 1652).

The horizontal position where the lower-lip mechanism touched the reed was controlled through the use of a ruler marked in millimeters and mounted close to the mechanism. A pointer attached to the lip mechanism moved along the ruler as its horizontal position was changed. The most advantageous position in this respect was located before any experiments began. This optimum position corresponded to the area where the reed left the facing of the mouthpiece when in its position of rest.

## Applied Ligature Pressure

A standard French metal ligature was used during the experiment and was secured to the mouthpiece by tightening two equally-spaced ligature screws. Care was taken to tighten the screws the same amount for each trial. The ligature was aligned with markings on the mouthpiece to ensure constancy of position from trial to trial.

## Mass and Density of the Reed

A Vandoren number 3 reed, carefully adjusted to respond well when played with a human embouchure, was used for all trials to ensure constancy in mass and density. The measure of elasticity of a mass, defined as the ratio of stress to strain (Reiman, 1971, p. 250) is a quantity known as "the modulus of elasticity." For linear deformations, as in the vertical movement of a vibrating reed, this modulus is known as Young's modulus (Reiman, 1971, p.250). Backus (1961) found that a wet reed has a smaller modulus, or smaller ratio of stress to strain. He wrote:

The Young's modulus for the cane from which reeds are made varies by more than a factor of two among samples, even for strips of the same cane. The density also varies, but over a smaller range. These variations make finding a good clarinet reed an unpredictable matter. The reed, when wet (as under playing conditions), has a smaller modulus and larger density than when dry (p. 1652).

Thus, a wet reed can be moved, or deformed, with less strain, than one which is dry. For this reason, the reed was kept wet during the experiment to simulate normal playing conditions. To maintain the wet state of the reed, an externally-controlled atomizer bottle was placed within the chamber and directed toward the reed/mouthpiece aperture. Also, because of large amounts of air entering the chamber during each trial, a wet sponge was placed on
the floor of the chamber to help stabilize humidity.

## Mouthpiece, Instrument, and Pitch

A standard Portnoy BP-02 mouthpiece with a medium facing was coupled to a plastic Bb Boehm system Vito clarinet in the experiment. Various pitches were attained by wiring keys shut and stopping the holes with rubber plugs. Care was taken to ensure that the ends of the rubber plugs did not protrude into the bore of the clarinet and that the depth of their penetration was kept the same for all holes.

## Loudness or Intensity

Intensity was monitored using a Realistic brand sound-level meter in a slow response mode. The slow response was selected since it presented an average intensity level over time, and, for purposes of this experiment, allowed more accurate measurerients to be taken. Since the loudness sensation produced by a vibrational amplitude depends on frequency, an A-weighted scale was used to register sounds in a way human ears hear. The A scale causes the meter to respond to changes in frequency, so as to be less sensitive to low and high frequencies. Backus (1977) states: "It has been found that readings with the A network correspond well to the subjective impression
of the listener to the sound measured" (p. 98).
For purposes of standardization in location, the sound-level meter was kept 30 cm from the clarinet bell and aimed directly at the instrument. The decibel levels chosen for the experiment were subjectively matched to music dynamic markings as follows: $90 \mathrm{dBA}=$ pianissimo $(\mathrm{pp}), 96 \mathrm{dBA}=$ mezzo-forte (mf), and $100 \mathrm{dBA}=$ fortissimo (ff).

Detailed Procedures

To evaluate the many aspects of reed vibration at various air pressures, a number of different procedures were necessary. Workcharts for these procedures may be seen in Appendix $B_{y}$, Tables 1 through 12. For clarity, these procedures are described below and are grouped according to specific aspects of reed vibration under observation. The procedures were completed for one pitch before advancing to the next, since lip pressure and position had to be changed between pitch levels. The various procedures discussed below were conducted one pitch at a time and in the sequence appearing on the worksheets. For clarity, the procedures are organized into two major categories: those centering around the effects of air-pressure variations and those centering around lip-pressure variations.

## Air-Pressure Experiments

## Preliminary Test of Natural Blowing Pressures

To compare air-pressure requirements of the artificial-embouchure chamber with those required in human performance, it was necessary to observe those pressures while the clarinet was being played in a natural manner, thus a preliminary test was conducted to determine natural air pressures required to produce tones throughout the range of the clarinet when blown by a human (see Appendix C). A plastic tube was inserted into a human mouth while playing the clarinet and connected to a U-tube water manometer. Air-pressure readings were observed for all pitches extending from E3 to G6 while an intensity level of 100 dBA was maintained.

Air-Pressure Variation and Intensity at Constant Lip Pressure

To determine the range of intensities possible through air pressure variations at constant lip pressure, two primary procedures were conducted.

In the first primary procedure, the lower-lip mechanism of the artificial embouchure was adjusted, in conjunction with air pressure, to produce a tone of high intensity (ff). With lip pressure held constant, air
pressure was reduced in small increments (approximately 2 cm H20) and data were recorded at each increment. This procedure was conducted on three pitches: F3, F5, and F6.

In the second primary procedure, the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a tone of low intensity (pp). With lip pressure held constant, air pressure was increased in small increments and data were recorded at each increment. This procedure was conducted on two pitches: F4 and B-flat 5.

To determine the influence selected lip-pressure settings might have on the results, the first primary procedure was repeated on F5 and the second primary procedure repeated on $F 4$, both with new lip pressure settings. To determine the effects that presetting lip pressure to an optimum setting might have on the results, the lower-lip mechanism was adjusted to an optimum pressure, which, in conjunction with air pressure, produced a tone of high intensity (100 dBA) on B-flat 5. Air pressure was then reduced to produce a tone of low intensity and slowly reapplied in small increments. Intensities were recorded at each increment of air pressure.

Air Pressure and the Vibrational Frequency of the Reed at Constant Lip Pressure

To observe the effects of air-pressure variations on the reed's frequency of vibration, the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a tone of low intensity ( 90 dBA ). Without changing the lower-lip mechanism, air pressure was increased to produce a tone of moderate intensity ( 96 dBA ), and again to produce a tone of high intensity ( 100 dBA ). Data were recorded at each intensity level. These tests were conducted on three pitches: F4, F5, and B-flat 5; and the data was presented in the form of a stripchart table. The reed's frequency of vibration at each pitch and intensity level was determined by multiplying the data rate times the total number of samples recorded within each cycle as shown on the stripcharts. Frequencies were compared across intensities and with a standard table of frequencies of pitches in the tempered scale (Backus, 1977, p. 153). The objective was to confirm, through quantitative data, that the reed vibrates at the frequency of the air column, regardless of the amount of applied air pressure.

Reed Amplitude and Intensity at Constant Lip Pressure

Before proceeding with experiments focusing specifically upon the effects of air pressure and reed amplitude, it was first necessary to observe the relationship between reed amplitude and intensity at constant air pressure. To simultaneously observe effects of air-pressure increases on reed amplitude and intensity, numerical representations (stripcharts) were produced from data previously collected on F4 (See "Air Pressure and Intensity at Constant Lip Pressure," second primary procedure), and used to calculate voltage peaks (reed amplitudes. Reed amplitudes were then compared to observed intensity (sound pressure) changes.

## Air Pressure and Amplitude of Reed Motion at Constant Lip Pressure

To observe the effects of air-pressure variations on amplitude of reed motion at constant lip pressure, the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a high-intensity tone of F4. Since the lower-lip mechanism was now set at an optimum pressure for a wide intensity range, the reed was in essence "spring-loaded" by the mechanism into a position conducive to efficient vibration. Air pressure was then reduced until the sound was no longer audible to a human ear, but
the pressure of the lower-lip mechanism was retained. Air pressure was then slowly increased in small increments of $2-3 \mathrm{~cm} \mathrm{H} 20$ until a sound was produced at the subjective threshold of hearing. Light-intensity variations received by the photo transistor were monitored and reproduced as graphs. These graphs were superimposed upon one another and the graphed light intensities were compared with air-pressure measurements.

## The transient.

An analysis of transient wave motion was made by combining two procedures. In the first procedure, a transient (a wave consisting of small reed vibrations which appear before an audible tone is initiated) was observed for the tone F 4 by slowly increasing air pressure after the reed had been "spring-loaded" to a pressure conducive to efficient vibration. A microphone was connected to the AC port of the digital converter and used to monitor any transient air-pressure variations which were produced. In the second procedure, air pressure was increased to produce a tone of high intensity and then lip pressure was withdrawn completely. The reed was allowed to continue vibrating, but at its own natural frequency (a squeal), undamped by the pressure of the lower-lip mechanism. Data were then collected via the microphone.

Data from these two procedures were compared by superimposing graphs of resulting wave forms. In this way, data for the F4 transient and the reed's natural frequency of vibration were recorded for comparison.

## Data on the steady state and air-column frequency.

Data from the F4 transient waveform demonstrated that it produced a fluctuation of greater wavelength than contained within the transient itself. To deteraine if this observed fluctuation might be an early product of the steady state (a tone, clearly of the vibrational frequency of F4, but not necessarily audible to the human ear), the waveform of the transient was superimposed over a waveform of air-pressure variations produced by the clarinet and measured with the microphone. The two waveforms were then compared. Graphs were also produced for four tones of low intensity (F3, F4, F5, and B-flat 5) in steady state.

## Lip-Pressure Experiments

## Lip Pressure and Intensity at Constant Air Pressure

Two procedures were conducted to observe the effects of lip pressure on intensity. In the first procedure (Appendix B, Table l, pages 07-10; for explanation of Table l, see Chapter IV, Data Forms), the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a wide range of intensities on the tone F3. Pressure exerted by the lower-lip mechanism was then increased until the clarinet was producing a tone of low intensity (70 dBA). Lip pressure was slowly reduced until it became so weak that the tone could no longer be maintained and intensity variations were recorded.

After completing the first procedure, it was observed that with the application of a constant volume of air to the artificial-embouchure chamber; air pressure, as measured within the chamber, varied as lip pressure was reduced. Therefore, a second procedure was conducted on F4 (Appendix B, Table 4, pages 08-10) in which air pressure within the chamber was kept constant. This was achieved by adjusting the potentiometer which regulated the speed of the air pump. In this procedure, the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a wide range of intensities. Pressure exerted by the
lower-lip mechanism was then increased until the clarinet was producing a tone of low intensity ( 80 dBA ). As applied lip pressure was reduced, air pressure within the chamber was maintained. Data were recorded at high and low lip pressures.

## Lip Pressure and Amplitude of Reed Motion

Using data previously collected on F3 (Appendix B, Table 1, pages 07-10), observations were made of the effects of lip-pressure variations on amplitude of reed motion. Four graphs were produced of the reed's motion as lip pressure was reduced in four increments ranging from high pressure to low pressure. Variations in reed amplitude were observed at each lip-pressure increment.

## Lip Pressure and Duration of Reed Closure

To observe effects of lip-pressure variations on duration of reed closure, two series of tests were conducted on the tone F3. In the first series, stripcharts were produced from data previously collected on F3 (Appendix $B$, Table 1 , pages $07-10$ ) in which lip pressure was slowly reduced in four increments. The lowest three voltages within each stripchart were selected as representing closure points. Air pressure and intensity were also monitored during the lip-pressure variations.

Graphs illustrating each waveform were produced.
In the second series of tests (Appendix B, Table 3, pages 00-11), two procedures were conducted on F3 using high and low lip-pressure settings. In the first procedure (Appendix B, Table 64, pages $06,08,10$ ), pressure of the lower-lip mechanism was set on a high-pressure setting. Air pressure was manipulated via the potentiometer to produce three intensities: threshold sound level, 90 dBA (mf), and 100 dBA (ff). The effects of high lip pressure on closure times were observed as applied air pressure was increased. In the second procedure (Appendix B, Table 3, pages $07,09,11)$, pressure of the lower-lip mechanism was set on a low-pressure setting. Air pressure was manipulated via the potentiometer to produce three intensity levels; threshold sound level, 90 dBA (mf), and 100 dBA (ff). The effects of low lip-pressure variations on closure times were observed as applied air pressure was increased.

CHAPTER IV<br>EVALUATION OF THE DATA

Graphic Representation of the Data

Graphic representations of the reed's vibrational cycle were compared for specific pitches at different air and lip pressures. A graphic representation of light fluctuations produced by a vibrating reed is shown in Figure 4. The vertical axis of the graph represents a continuum of light intensities which passed between the reed and mouthpiece, measured in millivolts. Since the numeric range of the data converter was 0 to 255, voltages produced by the photo transitor were presented graphically along a vertical scale comprising 256 increments. For purposes of this study, only relative voltage comparisons were made; therefore, the graphic representations do not include specific increments of voltage.

The horizontal axis represents passage of time in milliseconds. The amount of time depicted by the horizontal axis was adjustable in "steps" to expand or contract the waveform for graphic clarity. All graphic illustrations reproduced for this study were created at "step 1:" that is, 256 samples taken at the rate

Figure 4

> Light-Intensity Fluctuations for F4 $33.0 \mathrm{~cm} \mathrm{H} 20,90 \mathrm{dBA}$, Gain $=3.3$

F4 Tl 04
of 17,280 samples per second. Therefore, time separation between successive samples was $1 / 17,280$ (or . 0000579) of a second.

Each graph contains 256 samples or points, but since the Apple IIe computer could store 4096 samples at a time, samples were stored and presented in "sections" or "Pages," each containing 256 samples. The computer monitor could therefore be used to present a long stream of samples along the horizontal axis in sections of 256 samples each; i.e. page by page, or screen by screen. Page 5, for example, contained samples 1280 to 1535 ( 5 Pages x 256 samples per page, to 6 Pages x 256 samples per page, minus l). Therefore, each graph contains 256 possible samples within its vertical range and 256 samples within its horizontal range. The graphs are presented in an oblong shape only to facilitate spreading of the wave form. The frequencies, or hertz, of the graphic representations, are consistent by pitch; that is, $F 4$ in all graphs is equal to approximately 349.23 cycles per second (Backus, 1977, p. 153).

On the vertical scale, the analog-to-digital converter was designed to discriminate a maximum of 256 different voltage levels and to read these voltages to an accuracy of 0.4 percent of the total applied voltage. As light intensity received by the photo transitor increased, so did the voltage sent to the analog-to-digital converter. The converter also made switch-selectable gains available.

Gain refers to the amount of voltage amplification applied to the vertical scale of the graphs. The analog-to-digital converter offered gains of . $33,1.0,3.3,10,33$, and 100 times the incoming signal voltage received from the photo transistor. If the wave form was too flat for observation, it was possible to amplify the vertical aspect by increasing the gain on the converter. The objective was to adjust the gain control on the analog-to-digital converter until the voltage signal corresponded to the vertical range of the graph.

## Numeric Representation of the Data

A numeric representation of Figure 4 is presented in Table 1. Each numeric representation is identified as a "stripchart" and begins and ends on a selected sample number or "address." Table 1 represents a stripchart for F4 which begins with sample number 1024 and ends with sample number 1227, inclusive. This stripchart was created by selecting a "starting address" and an "ending address." This particular analysis shows only samples 1024 through 1227 from a total of 4096 samples. Table 1 displays only a portion of the samples contained within its corresponding waveform pictured in Figure 4.

On each stripchart, data are shown in six double-columns as indicated by the dotted lines, each double-column being comprised of two columns of values.

| 1047 | 45 | 1081 | 128 | 1115 | 49 | 1149 | 30 | 1183 | 121 | 1217 | 66 |
| 1048 | 38 | 1082 | 126 | 1116 | 55 | 1150 | 27 | 1184 | 119 | 1218 | 74 |
| 1049 | 33 | 1083 | 124 | 1117 | 62 | 1151 | 25 | 1185 | 115 | 1219 | 83 |
| 1050 | 29 | 1084 | 122 | 1118 | 69 | 1152 | 24 | 1186 | 112 | 1220 | 91 |
| 1051 | 26 | 1085 | 119 | 1119 | 77 | 115 | 23 | 1187 | 107 | 1221 | 99 107 |
| 1052 | 24 | 1086 | 116 | 1120 | 86 | 1154 | 23 | 1188 | 102 | 1222 | 107 |
| 1053 | 23 | 1087 | 112 | 1121 | 95 | 1155 | 25 | 1189 | 96 | 1223. | 113 |
| 1054 | 23 | 1088 | 109 | 1122 | 103 | 1156 | 25 | 1190 | 90 | 1224 | 119 |
| 1055 | 23 | 1089 | 103 | 1123 | 111 | 1157 | 27 | 1191 | 82 | 1225 | 123 |
| 1056 | 23 | 1090 | 97 | 1124 | 119 | 1158 | 28 | 1192 | 74 | 1226 | 126 |
| 1057 | 24 | 1091 | 90 | 1125 | 123 | 1159 | 29 | 1193 | 64 | 1227 | 127 |

The first value in the first row of column $l$ is the "point number" (sample number). The second value in the first row of column 1 represents light intensity in millivolts corresponding to each sample.

At the top of Table 1 are selected parameters prescribing the curve on page 04 of the entire data set of 4096 samples gathered. The starting address of 1024 denotes that samples from 0000 to 1023 are not shown. The ending address of 1227 denotes that samples beyond 1227 are not shown. This table, therefore, represents only the l024th sample through the l227th sample and their respective voltage values in millivolts. For purposes of symmetry in printing the tables, the ending address designated at the top of each table is three sample numbers lower than the sample number ending each table of data.

Each stripchart presented in this study begins with a starting address from which each corresponding graphic representation was developed. Therefore, each graph and its corresponding stripchart begins with the same sample number. The stripcharts, however, only present a representative portion of the 256 samples shown within each graph.

A survey of the sample values in Table 1 describes a fluctuation which corresponds to the sine curve in Figure 4. By carefully prescribing starting and ending addresses, any part of a graph may be scrutinized in much greater
detail with such a value representation. By noting time values and voltages shown within the graphs, accurate real-time measurements to $1 / 17,280$ of a second could be made of various positions of the reed. In this respect, this study was more comprehensive and microscopic than any presented to date.

## Data Forms

A data form was constructed (see Figure 5) to facilitate location of specific wave forms and to provide a log for each sampling. The heading of the form provided a space for indicating the pitch of the tone being studied. Because many tests were often run at the same pitch, a space was also provided for test number and date. The column designated as "Page" designated data Pages containing pertinent values which were briefly described by written observations notated at the end of each row. "Par" designated parameters (page numbers) which were entered into the computer to "call up" a specific data set. "L" and "R" designated water height in inches in the left and right columns of the U-tube manometer, respectively. "T" represented temperature within the embouchure chamber in degrees Centigrade. Sound pressure levels were notated in the column labeled "dBA." The column labeled "R-L, mm H2O" was used to notate air pressure derived by subtracting the water-level measurement observed within the left column of

the manometer from the water-level measurement observed within the right column. "EA" represented the "ending address" needed to observe the data set representative of a specific row or observation on the data form. Below the data form, "Disk Title, Data Name, Starting Address, Ending Address, Data Step, and Date" are found. This information allowed access to a data set via the computer. For example, a representative data form from which data in Figure 4 were extracted is shown in Appendix B, Table 6, Page 04.

## Analysis of Data Measurements

## Air Pressure and Intensity at Constant Lip Pressure

Analyses of intensity data showed that many intensities were attainable by increasing or decreasing air pressure within the embouchure chamber while keeping position and pressure of the lower-lip mechanism constant. To determine the range of intensities possible at constant lip pressure, intensity variations were monitored as air pressure was both increased and decreased in small increments (See Table 2).

In the first series of tests, the lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a tone of high intensity (ff) before air pressure was reduced. This procedure was conducted at three pitch

Table 2
Tests Using Two Primary Procedures
levels: F3, F5, and F6. Test 1 was conducted on the pitch F3 (Appendix B, Table 1, Pages 00-03). The clarinet was made to sound F3 at an intensity level of 98 dBA . Air pressure was reduced in small increments until the sound produced was at the threshold of audibility for a human ear. The resulting intensities ranged from 98 dBA to 68 dBA at constant lip pressure. If air pressure was reduced below 24.5 cm H 20 , the tone became inaudible; therefore, intensity range varied by 30 dBA for $F 3$ as air pressure was decreased at constant lip pressure.

Test 2 was conducted on F5 (Appendix B, Table 9, Pages 03-05). The clarinet was made to sound F5 at 100 dBA with an applied air pressure of $36.5 \mathrm{~cm} H 20$. It was possible to reduce air pressure to 31.5 cm H 20 before the tone faded to inaudibility. This yielded a 10 dBA intensity range. When this test was repeated on $F 5$ at a different lip-pressure setting (Appendix B, Table 9, Pages 06-07), similar results were attained. The intensity range available at constant lip pressure was again 10 dBA for $F 5$.

Test 3 was conducted on F6 (Appendix B, Table l0, Pages 00-01). Air pressure varied from $29.5 \mathrm{~cm} H 20$ to 23.5 cm H20 while intensity varied from 100 dBA to 96 dBA; a range of only 4 dBA. A further decrease in air pressure caused the sound to suddenly become inaudible. There was, therefore, a sharp decline in intensity level for $F 6$ when air pressure was reduced below 23.5 cm H 20 . It was not
possible, at the selected lip pressure, to sustain a tone at less than 96 dBA at $F 6$. The data from these three tests suggest that at constant lip pressure, the intensity range available from air-pressure reduction diminishes at higher frequencies.

To evaluate the effects of increases in air pressure on intensity at constant lip pressure, another series of tests were conducted. The lower-lip mechanism was adjusted, in conjunction with air pressure, to produce a tone of low intensity. With lower-lip pressure constant, air pressure was increased in small increments and data were recorded at two pitch levels: F4 and B-flat 5. Two tests were conducted at each pitch.

The first test was conducted on F4 (Appendix B, Table 5, Pages 00-05). Applied air pressure ranged from 21.5 cm H20 to 29.0 cm H 20 and produced intensities ranging from 80 dBA to 93 dBA ; a range of 13 dBA at constant lip pressure. When this test was repeated on F 4 at a different lip-pressure setting (Appendix B, Table $2, ~ P a g e s ~ 06-08)$, intensities ranged from from 72 dBA to 90 dBA ; a range of 18 dBA at constant lip pressure.

Test 2, on B-flat 5 (Appendix B, Table ll, Pages 08-11), allowed variations in air pressure ranging from 24 cm H20 to 31 cm H 20 , and produced intensities ranging from 90 dBA to 100 dBA ; a range of 10 dBA at constant lip pressure. These data suggest that at constant lip
pressure, the intensity range available by increasing air pressure diminishes at higher frequencies. In a second test on B-flat 5 (Appendix B, Table 12, Pages 02-08), the lower-lip mechanism was adjusted, in conjunction with air pressure ( 34.0 cm H 20 ), to produce a high-intensity tone of 100 dBA. Air pressure was lowered from 34.0 cm H 20 to 25.0 cm H20 to produce a tone of the lowest intensity audible to the human ear. As air pressure was then increased, a greater range of intensities resulted: from 90 dBA to 105 dBA; a range of 15 dBA at constant lip pressure. These data suggest that at constant lip pressure, intensity range may increase if lip pressure is preadjusted to a pressure conducive to the production of tones of high intensity. In summary (see Table 2), at constant lip pressure: a) intensity range available through air-pressure variations may increase if lip pressure is preadjusted to an optimum pressure, and b) intensity range available through air-pressure variations diminishes in the higher frequencies.

Air Pressure and the Reed's Frequency of Vibration at Constant Lip Pressure

To observe the effects of air-pressure variations on the reed's frequency of vibration at constant lip pressure, data were recorded at three intensity levels (90 dBA, 96 dBA, 100 dBA) and at three pitch levels (F4, F5, B-flat 5).

Stripcharts were produced for each pitch (Appendix B, Tables 13-21).

Test 1 was conducted on F4 (Appendix B, Table 6, Pages 00, 02, 04). Stripcharts were produced at three intensity levels ( 90 dBA, 96 dBA, 100 dBA ) as shown in Appendix $B$, Tables 13, 14, and 15. To determine the frequency of reed vibration at each intensity, it was first necessary to determine wavelengths. Wavelengths were determined by choosing a "starting-sample" number at a specific location within a wave and counting the total number of samples contained within one complete cycle of the wave. In Appendix B, Table 13, for example, sample number 19 was chosen as the starting sample since it was observed from the accompanying voltages that amplitude increased at this point. Sample number 19 became an arbitrary reference point within Table 13 where counting began. Additionally, observations showed that one cycle of vibration was completed at sample number 68, where voltages increased again to begin the second cycle. The total number of samples observed within this cycle was 50 samples. Since the data rate was 17,280 samples per second, the frequency of vibration was $(17,280 / 50)$, or 345.6 cycles per second. Utilizing this method of calculation, frequencies were determined for each pitch at each intensity level. A summary of these data is shown in Table 3. When F4 was sounded at an intensity of 100 dBA , each

cycle of reed vibration contained 50 samples, representing a frequency of 345.6 cycles per second. When $F 4$ was sounded at an intensity of 90 dBA , each cycle of reed vibration also contained 50 samples, again representing a frequency of 345.6 cycles per second. When these findings were compared with a frequency standard for $F 4$ within a tempered scale ( 349.2 cycles per second), it was observed that the reed consistently vibrated at a frequency for F 4. Similar results were observed for F5 and B-flat 5. Figures 6 and 7 illustrate the reed's vibrational patterns for B-flat 5 at 100 dBA and 96 dBA respectively. It can be observed from these figures that as air pressure decreased, amplitude decreased but wavelength remained the same. These data indicate that the reed vibrated at the frequency of the pitch being produced by the air column, and was not affected by air-pressure (intensity) increases. The slight differences between observed reed frequencies and the standard frequencies are negligible, indicating only slight intonation discrepencies which may have been produced by temperature variations within the chamber of the artificial embouchure or within the instrument.

Reed Amplicude and Intensity at Constant Lip Pressure

To observe the relatioinship between reed amplitude and intensity, graphs were produced (Figures 8-13) from data previously collected on F4 (See Appendix B,

Table 5, Pages 00-05) in which air pressure was increased in small increments. As air pressure was increased, intensity levels were monitored on the sound-level meter. Figure 8 illustrates the reed's vibrational cycles at 80 dBA which required an air pressure of 21.5 cm H20. In Figure 9, air pressure had been increased to 24.5 cm H 20 but produced only a slight increase in reed amplitude. An increase in intensity level was not observed. Figure 10 shows a dramatic increase in amplitude of the reed's motion as well as an increase in intensity level. In this case, a pressure of 26.0 cm H 20 produced an intensity level of 88 dBA. This trend continues in Figure ll. When an intensity of 93 dBA was reached, additional increases in air pressure did not produce subsequent increases in intensity. Figures 12 and 13 illustrate further increases in air pressure but lower reed amplitudes. Apparently, a saturation point was reached; further increases in air pressure only restricted the reed's movement. Intensity stablilized at 93 dBA for both air pressures.

Numeric representations of Figures 8 through 13 (and a second trial shown in Appendix B, Table 5, Pages 06-08), may be seen in Appendix B, Tables 22 through 30. Using these tables, comparisons were made between air-pressure increases and voltage peaks (reed amplitudes). For example, in Appendix $B$, Table 22 , the highest voltage produced between sample number (point number) 0 and 203 was

69 millivolts. This voltage represents the voltage peak for F 4 at 21.5 cm H 20 . Voltage peaks were collected in this way from Tables 22 through 30. These data are summarized in Table 4.

Table 4. Air Pressures vs. Peak Voltages for F4

These data suggest that as applied air pressure increases, amplitude of reed motion increases until a saturation point is reached, and that an increase in intensity does not always produce an increase in reed amplitude.

Data observed earlier regarding air pressure and the reed's frequency of vibration may explain these increases in amplitude. As air pressure within the player's mouth increases, more air must pass through the reed/mouthpiece aperture per unit time to equalize the pressure difference
between the player's mouth and the air column of the clarinet. Because the reed vibrates at the frequency of the air column to which it is attached, it cannot increase its frequency to accomodate the additional pressure of air molecules trying to escape through the aperture. Therefore the size of the aperture must increase in proportion to applied air pressure. This can be observed as an increase in reed amplitude. The compressibility of air molecules may play a minor role in this equation.

## Air Pressure and Amplitude of Reed Motion at Constant Lip Pressure

To observe the effects of air-pressure variations on reed amplitude, as opposed to intensity, it was necessary to keep the pressure exerted by the lower lip, as well as its position on the reed's surface, constant; since both factors might affect the reed's amplitude at a specific air pressure. In the following tests, where pressure and position of the lower lip were optimum for producing a wide intensity range, a gradual increase in applied air pressure caused the reed to react with a series of motions which were common to all pitches tested. Four stages were observable: the loading stage, the transient stage, the sinusoidal stage, and the closing stage.

## The loading stage

The loading stage was so-named because it described movements made by the reed before it began its vibrational cycle. The loading stage could not be successfully initiated until the reed was first "spring-loaded" into playing position by pressure from the lower-lip mechanism. This pressure bent the reed closer to the mouthpiece and held it there until air pressure was applied, at which point molecules of air rushed through the opening between the reed and the mouthpiece. As the velocity of air molecules past the tip of the reed increased, air pressure within the mouthpiece chamber was lowered as described by a principle of fluid mechanics first stated by Bernoulli (1700-1782). Zebrowski (1974) describes Bernoulli's principle as follows: "The pressure in a moving fluid depends on its elevation and on its velocity (p. 277)" i.e. the faster the rate of flow, the lower the pressure. Air pressure reduction within the mouthpiece chamber pulled the reed toward the mouthpiece at a rate which was proportional to the amount of applied air pressure. This can be clearly seen in Figure 14, created by superimposing eight different plots of light intensity passing between the reed and mouthpiece at various air pressures.

The reed was bent, or "spring-loaded" into position by pressure from the lower-lip mechanism before the experiment began. This preset pressure, necessary to engage the

Figure 14
Light Intensities at Various Air Pressures as Reed Moves Towards the Mouthpiece F4, Gain $=10$, ADC DATA XV

Bernoulli effect, was kept constant throughout the procedure. As air pressure was slowly increased, light intensity decreased proportionally, as shown in Figure 14. As the reed was drawn closer to the mouthpiece by the Bernoulli effect, the opening grew smaller, causing a proportional increase in molecular velocity through the venturi. When applied air pressure was stabilized, molecular velocity through the venturi also stabilized and the reed became motionless. This stabilization may be the consequence of a balance between applied air pressure, the "Young's Modulus" or elasticity of the reed, and the Bernoulli effect. As air pressure was stabilized, light intensity passing through the mouthpiece-reed aperture was recorded, producing light-intensity levels as shown in Figure 14. These levels represented distances the reed moved at various air pressures due to the Bernoulli effect and might therefore be used as proportional indicators of molecular velocity within the venturi at a specfic lip pressure. A direct relationship between voltage (light intensity) and applied air pressure can be seen in Table 5, comprised of voltage averages taken from Appendix B, Stripchart Tables 31 through 36. As air pressure increased, voltage averages decreased due to a reduction in reed/mouthpiece aperture.

Table 5
Voltage Averages vs. Applied Air Pressures

## The transient stage

To fully describe the tones produced by musical instruments, it was necessary to explore the initiation of tones. The begiñing of any tone can be scrutinized very closely by observing its transient state; the sound-wave pattern produced by the tone in the moments before the tone becomes stabilized or fully audible to the human ear. The transient stage exhibited the least amplitude of reed motion and formed quickly within a relatively narrow range of air pressures. In one cycle of vibration observed, applied air pressure caused the reed to move closer to the mouthpiece, thus reducing the opening between the reed and mouthpiece. As a result of this reduction in aperture, air
pressure within the venturi equalized with air pressure within the instrument and the elasticity of the reed began to pull it back to its primary position of rest. This position of rest was never quite reached however, due to force of the air pressure which was still being applied. Instead, the reed returned only part of this distance until it reached the point where the increasing velocity of air molecules through the venturi began to pull it back toward the mouthpiece again. These findings support visual observations made by Coppenbarger (1971), who stated: "Once the sound wave begins, the reed is affected by a Bernoulli condition. The excursion of the reed's tip from the mouthpiece during a vibration is not as large as the mouthpiece-reed gap with the playing embouchure pressure without sound" (p. 119). The reed/mouthpiece aperture levels observed during the loading stage in Figure 14 were characteristic of one specific lower-lip pressure setting. If lower-lip pressure had been increased, the reed would have been pushed into a preset position closer to the mouthpiece and greater air pressure would have been required to initiate the transient stage (See "Lip Pressure and Duration of Reed Closure").

The transient stage encompassed the transition from a non-vibrating state to one of vibration. A microphone was connected to the AC port on the digital converter and low air pressure applied to the artificial embouchure (Appendix

B, Table 8, Page 09). A transient for F4 was observed as shown in Figure 15. At low air pressure, the first vibrations to be observed were small, inaudible vibrations of the reed at its natural frequency. A regular fluctuation in amplitude is noticeable within the transient which matches the reed's natural frequency, shown in Figure 16. It can be seen from Figures 15 and 16 and their accompanying stripcharts in Appendix B, Tables 37 and 38, that amplitude fluctuations within the transient are partly comprised of the reed's natural frequency of vibration.

As the transient began to reach the steady state, a slight fluctuation of greater wave length became evident as shown in Figure 17. The voltage peaks of this wave form may seen in Appendix B, Table 39. When the wave form of the transient was superimposed over the waveform of a steady state $F 4$, it became evident that these longer wavelengths were the early products of the steady state. Figure 18 illustrates the steady state of $F 4$, and Figure 19, the superimposition. Although slightly out of phase, the early stages of the harmonic fundamental can be seen clearly. These observations support findings of Aschoff (1936) and Richardson (1954) that the reed's natural frequency is distinguishable within the steady state. Richardson (1954) writes: "Few wind instruments have transients which are exact copies of their steady states; either 'underblown tones' or 'reed partials' occur in the

first tenth of a second until overlaid by the principal tones of the column in its steady state" (p. 962).

The vibrations of the reed must eventually match the resonance mode of the instrument to which it is attached. Stubbins (1969) writes:

Because the harmonic frequency supplied by the tone generating system of the clarinet, matches the resonating or vibrational mode potential of a musical horn, all of the vibrational modes of the air column system are excited by the reed. However, the musical result is that which is obtained by the dampening effect of each of these modes, according to the shape of the air column involved. The shape of the air column reacts in turn, on the vibration pattern of the reed, which is the energy supplier for the sustaining system, and is so dominant, that in practice the tone-generating system of the clarinet is absolutely required to match the requirements of the clarinet to which it is attached, or the results are extremely inefficient (p. 59).

Evidence of this reactance may be seen in Figure 20. The tone of $F 4$ was produced with the artificial embouchure and measurements of light fluctuations produced by the reed were plotted. A plot of air-pressure variations produced within the clarinet sounding $F 4$ was made by connecting the microphone to the analog-to-digital converter. This plot of air-pressure variations was then superimposed over the plot of light-intensity fluctuations as shown in Figure 20. The reed's mode of vibration in the steady state closely matched the frequency produced by the air column.

Figure 20
Light Fluctuations for F4 Superimposed with Microphone Fluctuations for F4

F4, Gain $=33$, ADC DATA XVI

## The sinusoidal stage

The third stage of reed motion was the sinusoidal stage. It was produced by the cycle of events described above. For tones of low intensity, the wave forms appeared to be sinusoidal for all frequencies tested. Figures 21 through 24 provide examples of sinusoidal reed movement for low-intensity tones produced at four pitch levels at various air pressures.

## The closing Stage

When lip and air pressure were increased to specific degrees, the reed began to close on the mouthpiece. Two graphs were produced on F5 as illustrative examples. Figure 25 shows the reed just beginning to close completely, causing a flat line to appear within the cycle. With increased air pressure, the reed remained against the lay of the mouthpiece for a proportionally longer amount of time during each cycle. Is. Figure 26 , for example, the reed closed for almost half of its cycle. Eventually, at constant lip pressure, a saturation point was reached and closure time remained constant, regardless of further increases in air pressure. If lip pressure was subsequently increased, the reed was suddenly forced against the mouthpiece 100 percent of the cycle,

terminating the sound completely.
It was observed that when the reed closed against the mouthpiece, other vibrations were sometimes superimposed upon the reed when it reached maximum displacement. Apparently, these vibrations were caused by a physical reaction to the abrupt interruption of the reed's more efficient sinusoidal movement. These additional movements undoubtably contribute to the increased harmonic content of tones of greater intensity. Two graphs were produced on F3 as examples. Figures 27 and 28 show harmonic disturbances for F3 at two different intensity levels. Harmonic disturbance and amplitude increased as air pressure increased. This was found to be true for all pitches tested.

## Analyses of closure times

When air pressure was increased to a specific degree, the reed began to close completely on the mouthpiece during part of each cycle. It was observed from Figures 10 through 13 (see "The Effects of Air-Pressure Variations on Reed Amplitude and Intensity at Constant Lip Pressure") that application of greater air pressure increased the duration of time the reed remained closed.

For this reason, subsequent data were obtained on four pitches (F3, F4, F5, and B-flat 5) sounded at high intensity to determine the maximum percent of each cycle the reed can remain closed. Four tests were conducted on F3, four on F4, one on F5, and one on B-flat 5. The results are shown in Tabie 6. Figures 29 through 36, 12 and 13 are visual representations of these tests and Appendix B, Tables 40 through 49, their accompanying stripcharts. By counting samples included in the closed portion of each cycle, reed closure times were calculated for each wave period and compared across wave periods and pitches.

In Table 6, for example, contains four separate tests of $F 4$. Results of the first test are included in the stripchart number found in the row below the pitch designation: F4 Tl 04. This stripchart is located via the Lisc of Tables found at the beginning of Appendix $B$ which indicates the location as Table 44 (Appendix B). The third, fourth, and fifth rows under the pitch name in Table 6 indicate, respectively: applied air pressure, intensity level, and vertical gain used in producing the graphs.

By consulting the appropriate stripchart in Appendix B, Table 44 , the sample (point) values may be seen to fluctuate in regular intervals. For example, in column 1 of Appendix B, Table 44, a column of point numbers can be

seen starting with 1025. To the right of each point number is a corresponding voltage, beginning with 34 . These voltages decrease as follows: $34,20,10,6,5,5,5$, etc. The repeated values of 5 indicate that the reed stopped moving and closed on the mouthpiece. At point 1052 , voltages began to increase, reaching a peak at point 1058 with a voltage value of 76. Voltages stabilized again at point 1079 and the cycle, or period, was complete. A graphic illustration of this stripchart may be located by referring to the List of Figures and matching the stripchart number with the figure title. Therefore, a graphic representation of Appendix B, Table 44 may be seen in Figure 33. The first four dots or values at the left side of Figure 33 correspond to the first four values seen in the stripchart: $34,20,10,6$. The repeated values of 5 correspond to the flat portion of the wave as seen in the first quadrant of Figure 33.

The fourth row beneath F4 Tl 04 in Table 6 indicates that 50 samples were collected within the first period or cycle observed in the stripchart (Appendix B, Table 44). The fifth row indicates that 49 samples were collected within the second period. It can be seen from Table 6 that the number of samples comprising the first period of each wave closely matched the number of samples comprising the second period.

Samples also were counted within the flat portions of
each wave. These values are shown in the sixth and seventh rows of Table 6 as "Points Closing." As shown in Table 6, the number of samples comprising the closed portion of the first period closely matched the number of samples comprising the second period. By comparing samples comprising the closed portion of the first period with samples comprising an entire cycle, the percentage of time the reed remained closed on the mouthpiece was calculated and listed in the last row of Table 6.

These tests reflected a remarkable consistency when sample totals were compared between consecutive closure times and periods. F3 produced the longest closure time of the pitches tested, that being 48 percent. It was observed from Table 6 that for tones of high intensity, the reed remained closed on the mouthpiece for 37 to 48 percent of its cycle. For tones produced with a preselected lip pressure conducive to the production of a wide intensity range, no evidence was obtained that indicated the reed closes more than 48 percent of its cycle.

Specific time values were calculated for the closures. Appendix B, Table 44, indicates that a data rate of 6983 points (samples) per second were used when collecting these data for F 4 . The data step was 1 , indicating that samples were collected one at a time; therefore, the time between successive points on this stripchart is (1/6983) seconds, or 0.0001432 seconds, or . 14 milliseconds. Referring to

Table 6, it was found that for F3 Tl 00, the first period lasted for a total of 98 points, or 14 milliseconds (98 pts. $x 0.0001432 \mathrm{sec} . / \mathrm{pt} .=0.0140336 \mathrm{sec}$.$) . Closure time$ for the reed during this period was 6.73 milliseconds (47 pts. $\times 0.0001432 \mathrm{sec} . / \mathrm{pt} .=0.0067304 \mathrm{sec}$.$) , or 48$ percent of the first period ( $6,73 / 14=0.4807142=48$ percent). As shown above (See "Air Pressure and Amplitude of Reed Motion at Constant Lip Pressure"), when closure time for F 4 reached a certain percent, the system stabilized and amplitude remained constant, regardless of further increases in air pressure. Similar stabilizations are noticeable in Table 6. For example, in F3 T2 00, an applied air pressure of 24.5 cm H20 produced a reed closure of 48 percent. In F3 Tl 00, air pressure was increased to 36.5 cm H 20 but reed closure remained at 48 percent. These data (Table 6) indicate that at constant lip pressure and sufficient air pressure to cause reed closure, increases in air pressure can produce increases in reed closure times, until a closure time of 48 percent is reached. When closure time reaches 48 percent of a cycle, further increases in air pressure do not produce subsequent increases in closure, amplitude, $o x$ intensity, at constant lip pressure. Closure times of longest duration were observed for pitches of lower frequencies.

## Lip Pressure and Intensity at Constant Air Pressure

To observe the effects of lip pressure on intensity, two procedures were conducted. In the first procedure, F3 was sounded at very low intensity ( 70 dBA ) as shown in Appendix B, Table l, Page 07). Pressure exerted by the lower-lip mechanism was reduced in four stages and intensity variations were recorded. It was observed that as lip pressure was reduced, intensity increased from 70 dBA to 90 dBA ; a range of 20 dBA . Further reductions in lip pressure did not allow sufficient reed vibration and the tone was no longer sustained. The reed then entered its natural frequency of vibration and squeaking began. The investigator also observed that although the volume of air entering the chamber was constant, air pressure within the chamber decreased from 31.0 cm H 20 to 27.5 cm H 20 as lip pressure was reduced. Therefore, a second procedure was conducted on the tone F4 (Appendix B, Table 4, Pages 08-10). In this procedure, air pressure within the chamber was kept constant by adjusting the potentiometer which regulated the air pump. At a constant air pressure of 34.0 cm H20, lip-pressure reduction produced intensities from 80 dBA to 106 dBA; a range of 26 dBA . These data show that intensity range may be increased if air pressure is maintained within the chamber. Apparently, a player instinctively adjusts lip pressure
upon the reed as air pressure is varied. The range of intensity levels available through variations of lip pressure are impressive. Results support that intensity levels are controllable through a combination of lip and air-pressure variations.

## Lip-Pressure and Amplitude of Reed Motion

Using the same data collected previously on F3 (Appendix B, Table 1, pages 07-10), graphs of the reed's amplitude were produced at each lip-pressure increment as shown in Figures 37 through 40. In Figure 37, produced at maximum lip pressure, the reed appeared to be closing on the mouthpiece and exhibited a relatively small amplitude between closures. As lip pressure was reduced, reed amplitude increased dramatically as shown in Figure 38. Although a constant volume of air was applied to the artificial-embouchure chamber, air pressure within the chamber decreased from 31.0 cm H 20 to 29.0 cm H 20 when lip pressure was reduced. This reduction in air pressure may have resulted from a reduction of lip pressure on the reed and the subsequent increase of the aperture between the reed and mouthpiece, thus allowing more air to pass through the aperture during the open part of each cycle. Apparently, a direct relationship exists between the total area under the curve of Figures 37 and 38 , and the volume of air passing through the reed/mouthpiece aperture.

Therefore, an increase in the quantity of air passing through the aperture would simultaneously increase the Bernoulli effect.

A further decrease in lip pressure (Figures 39 and 40) increased reed amplitude to such an extent that the wave peaks were no longer within the scope of the graph. For this reason, gain (amplification of the vertical aspect of the graphs) was reduced from 33 to 3.3 , reducing the vertical aspect of the graphs by ten times. This second reduction in lip pessure increased amplitude of reed motion tenfold, increased harmonic disturbance within the waveform, and decreased air pressure within the artificial-embouchure chamber from 29.0 cm H 20 to 27.5 cm H2O .

A third reduction in lip pressure (Figure 40) did not reduce air pressure within the chamber, but increased reed amplitude and harmonic disturbance. These findings support the following observations: that with application of a constant volume of air, a reduction in lip pressure caused a lowering of air pressure within the chamber and produced an increase in reed amplitude and harmonic disturbance.

## Lip Pressure and Duration of Reed Closure

Using data collected previously on F3 (Appendix B, Table l, pages 07-10), stripcharts were produced to observe the effects of lip pressure on reed closure times. These stripcharts, which pertain to Figures 37 through 40, are found in Appendix B, Tables 50 through 53. The lowest three voltages in each stripchart were examined as representations of closure voltages since high sensitivity of the photo transistor caused these voltages to fluctuate slightly. These millivolt values are listed in the fourth column of the Table 7.

| Figure | cm H20 | dBA | Voltages | $\frac{\text { Points }}{\text { Selected }}$ |
| :---: | :---: | :---: | :---: | :---: |

Table 7
Point Totals for Reed Closures During Lip-Pressure Reductions

The point (sample voltage) totals illustrate that closure time was affected minimally by variations in lip pressure at a specific air pressure. Figures 37 through 40
seem to indicate that a reed's closure time on the mouthpiece is directly related to applied air pressure and is not dependent upon air pressure within the chamber or amplitude of the reed's motion. The resultant comparison is that applied air pressure exerted by the lungs of the player determines the closure time for a reed and this time is not appreciably affected by the amount of air being passed through the mouthpiece/reed aperture. These findings seem to indicate that an optimum resistance can be found when playing the clarinet if lip pressure is adjusted.

A second series of tests comprising two procedures were conducted on F3 (Appendix B, Table 3, pages 00-11) in which two lip-pressure settings (high and low) were used at three intensity levels: threshold sound level, 90 dBA (mf), and $100 \mathrm{dBA}(f f)$. In the first procedure, pressure of the lower-lip mechanism was set on a high-pressure setting. Air pressure was manipulated via the potentiometer to produce three intensities. In the second procedure, pressure of the lower-lip mechanism was reduced and set to the low-pressure setting. Air pressure was again manipulated to produce three intensities. Therefore, high and low lip-pressure settings were kept constant across intensities and only applied air pressure was varied.

Table 8
Point Totals for Reed Closures At Two Lip-Pressure Settings for F3

Only a slight reduction in closure points is noticeable when lip pressure is reduced and the intensity level is maintained. As expected, air pressure within the chamber dropped slightly as lip pressure was reduced and amplitudes rose dramatically as seen in Figures 43, 44, 45 and 46. The data support that an increase in reed amplitude does not always produce an increase in intensity
level. Pressure exerted by the lower lip is a critical factor. If pressure of the lip is decreased, slightly less air pressure is required to maintain the same intensity level, and conversely.

Figures 45 and 46 illustrate $F 3$ at 100 dBA but with different lip pressures. In Figure 45, amplitude was much less than in Figure 46, yet intensity level remained the same. These findings may indicate that as more lip pressure is applied, lip tissue flattens out and exerts a dampening effect on amplitude of reed vibration. At the same time, closure time is slightly increased as if the dampening effect has transformed lost amplitude into a relatively small amount of closure time. Duration of closure exhibited by the reed must therefore be viewed as one of high pressure, which, when finally released, produces a relative amplitude which is proportional to the time and pressure exerted upon it during the duration of its closure.

Air-Pressure Requirements for Low-Intensity Tones at Two Lip-Pressure Settings

Using data collected previously on F3 (Appendix B, Table 3, pages 07-11), air-pressure requirements for producing tones at the threshold of hearing were observed at high and low lip-pressure settings. Figures 41 and 42 (see "Lip Pressure and Duration of Reed Closure")
illustrate threshold sounds which are bordering on closure. The wave form in Figure 41 was lower than that in Figure 42 because higher lip pressure had almost forced the reed closed. These wave forms clearly indicate that a low-intensity tone (ppp) may be initiated with less loss of air pressure from the mouth (more resistance) by closing off the reed with more lip pressure. These findings support those of Backus (1962). He stated:

The threshold blowing pressure is directly proportional to the reed opening and reed stiffness, and is modified somewhat by the $Q$ [air friction on the internal walls] of the instrument. It does not vary with the reed damping, for example, and should therefore not depend on the condition of the player's lip (p. 312).

If a low-intensity tone is initiated at low lip pressure, persistent loss of air pressure in the mouth and the rush of air into the mouthpiece aperture produces a tone often described by clarinetists as being "spread." A more "focused" low-intensity tone may be produced by closing off the reed with more lip pressure as shown in Figure 41. Since most low-intensity tones, especially in the low register of the clarinet, consist largely of the fundamental, the "spread" feeling described by clarinetists could be due to air loss through the reed/mouthpiece aperture when lip pressure is insufficient to reduce this aperture to a minimum. These findings support those of Ghosh (1938), who provided mathematical evidence showing that a clarinetist can control clarinet tone quality by
slightly increasing or decreasing the pressure of the lip upon the reed. According to Ghosh, this varied the width of the "chink" or space between the reed and the mouthpiece and in turn varied the effective vibrating length of the reed. He hypothesized that this variance in the effective vibrating length may alter the series of harmonics which are produced, thus increasing or decreasing the number and strengths of harmonics present in the tone.

## CHAPTER V

SUMMARY AND CONCLUSIONS

## Summary

The purpose of this study was to observe effects of air and lip-pressure variations on the vibrational patterns of a single reed. In the interest of investigating specific characteristics of reed motion such as intensity, amplitude, and closure, the study was not meant to be statistically conclusive. To facilitate observations, a blowing chamber containing an artificial-embouchure device was constructed into which a clarinet could be inserted and sealed at the barrel joint. A direct-current light source was focused through the bell end of a clarinet, through the reed-mouthpiece aperture, and into a photo transitor mounted within the chamber 2 millimeters from the aperture of the reed and mouthpiece. Light fluctuations produced by the reed's movement on the mouthpiece were detected by the photo transitor and converted into voltages, which were then converted to digital signals by a Nalandata analog-to-digital converter. The analog-to-digital converter was interfaced with an Apple IIe computer and used in conjunction with "Apple-Swiss" softwear developed by Nicklin (1986) to produce graphic representations of the
variations in light intensity received by the photo transistor. The procedures were divided into two major categories: air-pressure experiments and lip-pressure experiments.

## Air-Pressure Experiments

## Natural Blowing Pressures

A preliminary test was conducted to determine natural air pressures required throughout the range of the clarinet (See Appendix C). A plastic tube was inserted into a human mouth while playing the clarinet and connected to a U-tube water manometer. Air-pressure measurements were observed for all pitches from E3 to G6 while maintaining an intensity level of 100 dBA. This test was conducted to compare blowing pressures required when a human plays the clarinet with those required by the artificial-embouchure device.

## Air-Pressure Variation and Intensity at Constant Lip Pressure

Two primary procedures were conducted to determine the range of intensities possible by multidirectional manipulation of air pressure at constant lip pressure. In the first procedure, the lower-lip mechanism of the artificial-embouchure chamber was adjusted, in conjunction
with air pressure, to produce a tone of high intensity. Air pressure was then reduced in small increments and the range of intensities was observed. This procedure was conducted on three tones (F3, F5, and F6) and provided baseline data on functional intensities. In the second procedure, the lower-lip mechanism of the artificialembouchure chamber was adjusted, in conjunction with air pressure, to produce a tone of low intensity. Air pressure was then increased in small increments and the range of intensities was observed. This procedure was conducted on two tones: F4, B-flat 5. These two primary procedures were conducted to determine the range of intensities possible through air-pressure variations at constant lip pressure and were repeated on $F 4, F 5$, and $B-f l a t 5$ to determine the influence selected lip-pressure settings might have on the results.

Air Pressure and the Vibrational Frequency of the Reed at Constant Lip Pressure

To observe effects of air-pressure variations on the reed's frequency of vibration at constant lip pressure, air pressure was manipulated to produce three intensities (90 dBA, 96 dBA , and 100 dBA ) on three tones: $\mathrm{F} 4, \mathrm{~F} 5$, and B-flat 5. Using stripcharts of voltages produced by the photo transistor, the reed's frequency of vibration at each pitch and intensity level were determined. Frequencies
were compared across intensities and with a standard table of frequencies for pitches in the tempered scale (Backus, 1977, p. 153) to determine whether the reed's frequency of vibration was the same frequency as the tone being produced.

## Reed Amplitude and Intensity at Constant Lip Pressure

To observe the relationship between reed amplitude and intensity, stripcharts were produced from data previously collected on F4 and used to calculate voltage peaks (reed amplitudes). Reed amplitudes were then compared to intensity changes as monitored on a sound-level meter. This procedure was conducted to observe variations in reed amplitude and intensity as air pressure was varied so that a relationship between reed amplitude and intensity might be established before further, and more focused, investigations were initiated.

## Air Pressure and Amplitude of Reed Motion at Constant Lip Pressure

To observe the effects of air-pressure variations on amplitude of reed motion at constant lip pressure, the lower-lip mechanism was set at an optimum pressure for producing a high-intensity tone of F 4 . Air pressure was then reduced until the sound was no longer audible to a
human ear, but the pressure of the lower-lip mechanism was retained. Air pressure was slowly increased in small increments until a sound was produced at the subjective threshold of hearing. Light-intensity variations received by the photo transistor were produced as graphs and superimposed upon one another. The charted levels of light intensity were compared with air-pressure measurements to determine the effects air pressure might have upon reed amplitude.

The Transient

Data were collected for light fluctuations on a transient tone for F4 and compared with air-pressure variations of the reed's natural frequency of vibration collected via a microphone interfaced with the computer. By superimposing graphs of the resulting wave forms, data for the F4 transient were compared with the reed's natural frequency of vibration and the steady-state wave form for F4.

## Lip-Pressure Experiments

## Lip Pressure and Intensity at Constant Air Pressure

Two procedures were conducted to observe the effects of lip pressure on intensity. In the first procedure, without keeping the air pressure within the chamber constant, applied lip pressure was reduced from a high setting to a low setting and intensity range was observed. Upon the determination, from observations of the results, that air pressure within the artificial-embouchure chamber varied as lip pressure was reduced, a second procedure was conducted. In the second procedure, air pressure within the chamber was kept constant, and applied lip pressure was again reduced from a high setting to a low setting. Intensity changes were observed and compared with the findings in the first procedure.

## Lip Pressure and Amplitude of Reed Motion

Using data previously collected on F3 in which lip pressure was reduced in four increments, observations were made of the effects of lip-pressure variations on amplitude of reed motion. Graphs were produced and amplitudes were visually compared at each lip-pressure increment.

## Lip Pressure and Duration of Reed Closure

To observe effects of lip-pressure variations on duration of reed closure, two series of tests were conducted on the tone F3. In the first series, using stripcharts produced from data previously collected on F3, closure times were studied by observing selected voltages representing closure as shown on the stripcharts. In the second series of tests, air pressure was manipulated to produce three intensities (threshold sound level, 90 dBA , and 100 dBA) at two lip-pressure settings. Stripchart voltages were then studied to observe duration of reed closure at two lip-pressure settings.

## Conclusions

Based upon observations, conclusions are categorized and listed below.

## General Observations of Reed Motion

1. At specific air and lip pressures, the reed completely closed on the mouthpiece during its cycle of vibration.
2. For low-intensity tones in all registers, the motion of the reed produced a wave form which was sinusoidal.
3. For high-intensity tones in all registers, the motion of the reed produced a square-wave form, showing that
the reed closed on the mouthpiece for a portion of its cycle.
4. When the reed closed against the mouthpiece with a specific force, smaller vibrations were superimposed upon the reed's waveform when it reached maximum displacement. These additional movements undoubtably contributed to increased harmonic content in tones of greater intensity.
5. The reed's mode of vibration in the steady state matched closely the mode of the air column.
6. The reed's natural frequency of vibration was distinguishable within the steady state.
7. Small inaudible vibrations of the reed at its natural frequency, combined with reed partials, were evident before the reed began to follow the requirements of the air column.

## Air-Pressure Experiments

1. At constant lip pressure, an increase in air pressure increased amplitude of reed motion but did not affect the reed's frequency of vibration.
2. At constant lip pressure, a continual increase in air pressure eventually caused the reed to close on the mouthpiece during its cycle of vibration, but its frequency of vibration remained constant.
3. At constant lip pressure, an increase in air pressure
produced an increase in closure time.
4. Four stages were observable when air pressure was applied to the reed: the loading stage, the transient stage, the sinusoidal stage, and the closing stage.
a. The loading stage, necessary to engage the Bernoulli effect while preventing the reed from vibrating at its own natural frequency, was created by pressure exerted on the reed by the lower lip before playing began.
b. The transient stage was observed to have the least amplitude of reed motion and formed quickly within a relatively narrow range of air pressures. The reed's frequency of vibration remained constant as the transient formed.
c. The sinusoidal stage was observed to be a characteristic model of the vibrational cycle of the reed before closure began.
d. The closing stage was the observed motion of the reed when it closed completely on the mouthpiece. In this stage, reed motion produced a wave form which closely resembled a square wave.
5. When the clarinet was played by a person, there was a noticeable decrease in air pressure required to maintain the same intensity level in the low register as in the high register, thus specific pitches required more air pressure to maintain an equal intensity level
with neighboring pitches.

## Lip-Pressure Experiments

1. With the application of constant air pressure, a reduction in lip pressure caused a decrease in air pressure within the artificial-embouchure chamber and an increase in reed amplitude and intensity level. The frequency of reed vibration remained constant as lip pressure was reduced.
2. There was minimal change in closure time observed when air pressure was held constant and lip pressure was reduced. Lip-pressure reduction did not appreciably affect closure times and the frequency of reed vibration remained constant.
3. Lip pressure influenced hearing-threshold sound pressures only slightly and not to the degree that it affected sounds of greater intensity. Often, the same air pressure initiated a sound at different lip pressures.
4. Air pressure increased within the artificial-embouchure chamber as lip pressure increased because less air escaped between the reed and mouthpiece.
5. A low-intensity tone (ppp) was initiated with less loss of air pressure from within the artificial-embouchure chamber when the reed/mouthpiece aperture was reduced with more lip pressure. This, in effect, created more
resistance within the system. Therefore, lip pressure becomes an important factor in regulating the amount of resistance a player desires for a specific tone quality.

## Duration of Closure

1. Reed closure began at lower air pressures for tones of higher frequency.
2. At specific air and lip-pressures, the reed never closed more than 48 percent of a cycle, regardless of frequency or intensity level.
3. There was great consistency in closure times from cycle to cycle within the same wave.

## Amplitude and Intensity

1. An increase in reed amplitude did not always produce an increase in intensity level, therefore, lip pressure may be an important factor affecting amplitude at specific air pressures.

## Implications of the Study and Pedagogical Applications

#### Abstract

At present, the pedagogy of the clarinet is comprised of a complex, often confusing, variety of teaching strategies. Teachers of the clarinet remain very individualistic in their ideas regarding the proper parameters leading to success in performance. Some teachers may concentrate on tone quality at the expense of technique, while others may insist on technical agility at the expense of tone quality. This dichotomy may have emerged from a lack of understanding among players as to how the many physical aspects of tone production must be tempered to work together. The findings of the present study indicate that the parameters for lip and air pressure, when considering the simple production of sound, are rather broad. With the ever-increasing body of scientific research literature regarding the clarinet, very specific physical criteria must be researched to verify the success of pedagogical practices. More research is needed to bring these physical criteria into focus for the teacher of the clarinet so that some of the subjectivity which surrounds highly successful clarinet teaching and performance may be eliminated.

## Recommendations for Further Research

As shown in the present study, the interaction of air and lip pressure in producing a specific pattern of reed motion is crucial; consequently, specific theories presented in the past need to be reevaluated in the light of these new findings. New questions have emerged which invite further inquiries into the characteristics of reed motion at different lip positions. Lip position, held constant in the present study, may add another dimension to our present understanding of reed motion at specific air and lip pressures. When a mouthpiece is inserted further into the player"s mouth, the lower lip comes into contact with the reed at a lower point, thus leaving more of the reed's surface free to vibrate. Might a practical method be discovered, through empirical means, of predicting and locating an ideal lip position, which takes into consideration the internal and external dimensions of the mouthpiece? Might different lip positions on the mouthpiece and reed alter the findings of the present study regarding air and lip-pressure requirements under specific conditions? Questions also remain unanswered concerning damping effects of the lip upon the reed. Might damping effects contribute to closure times at specific air and lip pressures?

Interesting theories have abounded regarding the
pedagogy of tongue position and its relation to the production of tone quality when playing the clarinet. One curious aspect of these theories is the presumption on the part of some teachers that the shape of the tongue increases the velocity of air across the reed/mouthpiece aperture and changes, possibly through damping effects, the "color" of the tone which is produced. To date, accurate measurements of air velocity across the tip of the reed have been impossible; partly because of a lack of technology which is damanded for such a measurement, and partly because of difficulties encountered when attempting to acquire measurements in an area as small as the oral cavity. Even with the availability of highly sensitive transducers, artificial-embouchure devices, and computers, the feasibility of acquiring such a measurement is limited. The present study, however, opened some interesting alternatives regarding the measurement of velocity across the reed whch might be expanded into a functional method of measurement. For example, when applying a slow increase of air pressure to a reed which was preset into playing position (loading stage), a reduction in reed/mouthpiece aperture was directly proportional to the amount of applied air pressure. Would not the reverse be true? Might this observation be used in reverse, so that observable changes in the reed/mouthpiece aperture, under specific conditions, could be used as an indicator of variations in molecular
velocity across the reed? Mooney (1968) used an artificial-embouchure device to study wave forms of the tones produced when an artificial tongue was placed near the reed. In conjunction with the theory presented above, this method might be used to determine whether tongue placement has an effect on the tone quality which is produced. Such an investigation would have important pedagogical implications.

APPENDIX A
DESCRIPTION OF SOFTWARE

## Description of "Apple Swiss" Software

The "Apple Swiss" software used in this study was produced by Nicklin (1986) at Appalachian State University and is distributed by Nalan Computer Specialties (106 Highland Park Lane, Boone, N.C., 28607). The software program is designed to accompany the Nalandata A2 Data Converter Unit (see description in text in Chapter III, "Data Converter Specifications"). Using this software, digitized signals from the data converter can be manipulated (integrated, differentiated, normalized, compared with another signal, or simply stored) for printout, for storage on disk or tape, or for display on the video screen. The brief description of "Apple Swiss" applications which follow are only a small sample of possible applications offered within the software program. The main menu of the software program offers a variety of visual formats for the data. One may select parameters of the data set, the rate of samples to be collected per second, and memory range to be used. The menu offers a "scope" option which converts the screen of the computer into a real-time oscilloscope so that data being received from a transducer may be observed directly. By pushing any key on the computer's keyboard, data is taken, under preselected parameters, and stored within the computer. Via another memu option, data collected may be graphed,
page by page (for description of "pages," see Chapter IV, "Graphic Representation of the Data"), or screen by screen. Using "Triple Dump" (1984) by Beagle Bros. Inc., any "screen" of data may be converted to hard copy via a variety of parameter settings. Another menu option offers hard copy of data in the form of "stripcharts." Data may also be observed in a low-resolution plot called a "glass stripchart." Screens (or pages) of data may be superimposed upon one another for comparison, and hard copy is available of the superimpositions. The versatility of the program is notable. The softwear package is available with a manual and an Nalandata A2 Data Converer Unit from the address shown above.

## APPENDIX C

NATURAL BLOWING PRESSURES

## Analyses of Natural Blowing Pressure Tests

It was observed that with the A-weighted scale in operation, the fortissimo of 100 DbA measured by the sound-level meter was not always in accordance with the subjective dynamic sensitivity of the ear of the performer. A chromatic scale was played slowly (quarter note $=\operatorname{mm} 40$ ) (by human means) and tape recorded while maintaining a constant 100 DbA. Upon playback, it was very noticeable that the scale did not sound dynamically consistent to the writer, although most of the pitches sounded within the mf to ff range. The blowing pressures observed are listed in Table C-1. The pitches listed are transposed (i.e. E3 would sound D3).

> Table C-l
> Mouth Pressures for Various Pitches of High Intensity

| Pitch | cm H20 | Pitch | Cm H20 |
| :--- | ---: | :--- | ---: |
|  |  |  |  |
| E3 | 53.0 | C5 | 42.0 |
| F3 | 51.0 | C\#5 | 44.0 |
| F\#3 | 51.0 | D5 | 51.0 |
| G3 | 44.0 | D\#5 | 37.0 |
| G\#3 | 48.0 | E5 | 37.0 |
| A3 | 51.0 | F5 | 37.0 |
| A\#3 | 42.0 | F\#5 | 39.0 |
| B3 | 44.0 | G5 | 35.0 |
| C4 | 48.0 | G\#5 | 35.0 |
| C\#4 | 62.0 | A5 | 33.0 |
| D4 | 48.0 | A\#5 | 33.0 |
| D\#4 | 48.0 | B5 | 28.0 |
| E4 | 42.0 | C6 | 30.5 |
| F4 | 46.0 | C\#6 | 30.5 |
| F\#4 | 51.0 | D6 | 28.0 |
| G4 | 46.0 | D\#6 | 28.0 |
| G\#4 | 46.0 | E6 | 28.0 |
| A4 | 46.0 | F6 | 30.5 |
| A\#4 | 60.0 | F\#6 | 30.5 |
| B4 | 42.0 | G6 | 33.0 |

There was a noticeable decrease in the amount of air pressure required to maintain the same intensity level in the low and high registers. It was noted that specific pitches required more air pressure to maintain an equal intensity level with neighboring pitches. These pitches (C\#4, F\#4, A\#4, D5) are notorious among clarinetists as being "bad" tones on the Boehm system clarinet in terms of tone quality. An example is C\#4, which required 62 cm H 20 , as compared to pitches in close proximity to it, C4 and D4, each of which required 48 cm H20. Similar cases may be found for $F \# 4, A \# 4$, and D5.

Pressures used by McGinnis and Gallagher (1940) ranged from 1.6 cm to 3.6 cm of mercury. Converted into centimeters of water, this would be equivalent to a range of 22 cm to 49 cm :

Density of $\mathrm{H} 20=1.000 \mathrm{~g} / \mathrm{cm} 3$ Density of $\mathrm{Hg}=13.55 \mathrm{~g} / \mathrm{cm} 3$

$$
\begin{aligned}
& 1.6 \mathrm{~cm} \mathrm{Hg} \times 13.55=21.68 \mathrm{~cm} \mathrm{H} 20 \\
& 3.6 \mathrm{~cm} \mathrm{Hg} \mathrm{x} 13.55=48.78 \mathrm{~cm} \mathrm{H} 20
\end{aligned}
$$

Backus (1961) found that blowing pressure for a clarinet as sounded by an artificial embouchure was between 5 and 20 inches of water ( $10-40 \mathrm{~mm} \mathrm{Hg}$ ). Converted to cm H 20 , this would represent a range of 13 cm H 20 to 52 cm H 20 .

5 inches $\mathrm{H} 20 \times 2.6 \mathrm{~cm} /$ inch $=13 \mathrm{~cm} \mathrm{H} 20$
20 inches $\mathrm{H} 20 \times 2.6 \mathrm{~cm} /$ inch $=52 \mathrm{~cm} \mathrm{H} 20$
or:
$10 \mathrm{~mm} \mathrm{Hg}(1 \mathrm{~cm} \mathrm{Hg}) \times 13.55=13.55 \mathrm{~cm} \mathrm{H} 20$
$40 \mathrm{~mm} \mathrm{Hg}(4 \mathrm{~cm} \mathrm{Hg}) \times 13.55=54.20 \mathrm{~cm} \mathrm{H} 20$

Backus noted that "the same range of pressures is required for blowing the clarinet by mouth" (p. 806).

An average range of blowing pressure for the clarinet was reported by Broadhouse (1892) as being "15 to 18 inches of water" (p. 229). Mooney (1968) concluded that "clarinetists use slightly different air pressures in the mouth to produce tones at the same "volume" and pitch. Air pressure decreases as the high register is approached" (p. 2742). Bouhuys (1964) noted that "measurements of mouth pressures and air-flow rates during play on various wind instruments have shown a wide range of variability. In most instruments, mouth pressures increase with both
frequency and sound output" (p. 453). This would seem to be in disagreement with findings of Bouhuys as well as with the findings above. In summary, it was observed that air-pressure requirements for sounding a clarinet via an aritificial-embouchure device were consistent with air-pressure requirements for a clarinet as blown by a human.
