**Abstract:**

Background: Past research has shown discrepancies between the time of symptom onset for patients with acute coronary syndrome (ACS) as documented in the medical record (MR) and patients’ recall of the time assessed through subject interviews done later by researchers.

Purpose: The aim of this study is to determine if there were differences between the time of symptom onset documented in the MR and subject interview taking into consideration sex, age group, and recall period for patients admitted to the emergency department for symptoms suggestive of ACS.

Methods: A secondary analysis was conducted on data from the PROMOTION (Patient Response to Myocardial Infarction Following a Teaching Intervention Offered by Nurses) trial, a multicenter randomized clinical trial to reduce patientprehospital delay to treatment in ACS.

Results: Of the 3522 subjects with CAD enrolled into the trial, 3087 subjects completed 2-year follow-up. Of these, 331 subjects sought treatment in the emergency department for ACS symptoms and 276 patients (83%) had complete information on the time of symptom onset from both sources. Of the 276 patients, 25 (9%) had differing times more than 48 hours and were thus excluded. The median difference between the 2 sources was 45.0 minutes. When both times were examined, there were no significant differences in time by sex (P = .720) or by age group (P = .188). The median number of days between the interview and the date of symptom onset was 29.5 days. There was a significant correlation between differences in the time of symptom onset and the length of recall period (rs = 0.148, P = .023). In multivariable modeling, a longer recall period was associated with greater median differences in the symptom onset time (b = 13.2, P = .023).
Conclusion: These results suggest that the time of symptom onset obtained at the time of the index event and documented in the MR is not interchangeable with data obtained later by research staff, especially if the interview is not conducted near the time of the index event.

Article:

The time of symptom onset for patients with acute coronary syndrome (ACS) is frequently used to calculate total ischemic time, defined as the time of symptom onset to the time of the first coronary artery balloon inflation. Total ischemic time could be influenced by patient-related delays, such as when patients fail to recognize and act upon symptoms of ACS, or hospital-related delays, such as when clinicians fail to diagnose patients in a timely manner once they enter the health care system. Either type of delay influences whether patients with ACS are eligible for acute reperfusion therapy. The longer the total ischemic time, the larger the infarction and the worse the patient outcomes are. For example, total ischemic time has been shown to correlate better with infarct size and mortality compared with the door-to-balloon time interval in patients with ACS.1

Total ischemic time has been identified as 1 criterion of quality care for patients with ACS. Thus, accuracy in collecting and documenting this time interval by clinicians to maximize patient outcomes and demonstrate quality care is important. The time of the first coronary balloon inflation is relatively easy to define and obtain from the medical record (MR). However, a challenge remains in how consistent hospitals across the country operationally define the time of symptom onset with patients with symptoms of ACS. In fact, the American College of Cardiology Foundation/American Heart Association Task Force on Clinical Data Standards advocates a consistent definition for the time of symptom onset as the time when the patient first notes ischemic symptoms lasting 10 minutes or longer.2

In addition, cardiovascular researchers who investigate prehospital delay in patients with ACS frequently use the time of symptom onset to calculate prehospital delay time as an outcome variable for their research. When designing their studies, researchers have to decide whether to obtain these data from the MR, to interview subjects themselves, or to combine the 2 sources to obtain more complete data. Each source has the potential for measurement error.

Some researchers consider the MR to be the “gold standard” because these data are collected and documented in “real time” and thus are less subject to recall bias. However, the MR is designed for clinical use, and data obtained from this source may be limited by legibility, completeness, and accessibility. Past studies have shown that the percentage of missing or incomplete symptom onset data in the MR for patients with acute myocardial infarction ranged from 14% to 40%.3-7 Furthermore, patients who are older and are female are more likely to have missing or incomplete time of symptom onset data in the MR.3
METHODS

This secondary analysis was conducted on data from the PROMOTION (Patient Response to Myocardial Infarction Following a Teaching Intervention Offered by Nurses) trial. The PROMOTION trial, a randomized clinical trial, tested a face-to-face intervention designed to reduce patient delay in seeking treatment for ACS symptoms. Patients with a history of cardiac disease were enrolled, randomized to usual care or intervention and then followed for 2 years for occurrence of ACS symptoms. Patients were instructed to call the investigators (after the acute event was over) when they sought treatment for symptoms they believed were cardiac in origin. In the event that patients did not contact the investigators after an ED visit, patients were also telephoned every 6 months by investigators to discuss whether there had been any unreported ED visits for ACS. Patients who sought treatment for symptoms for presumed ACS were interviewed
using techniques that the investigators had developed to assist patients most closely determine the time of symptoms onset.

SAMPLE

Of the 3522 patients with a history of CAD who were enrolled in the PROMOTION study, 3087 (88%) completed 2-year follow-up. Of these, 565 had ED admissions with symptoms suggestive of ACS. Of the 565 patients, 331 (59%) were diagnosed with ACS (and these were included in the current study). Among these 331 patients, 11 (3%) were missing time of symptom onset in the MR and 48 (15%) were missing the time of symptom onset from subject interviews; thus, 55 patients (17%) were missing data from either MR or subject interview.

A total of 276 patients (83%) had complete data from both sources. Of these patients, for 25 (9%), there was a difference of more than 48 hours in time of symptom onset reported in the MR and the interview. Because this difference was so large, these patients were not included in the analysis. The remaining sample of 251 ACS patients is the focus of this report.

DATA ANALYSIS

Patient sample characteristics were assessed using descriptive statistics. Differences in time of symptom onset between the MR and interview were calculated in minutes and were categorized as less than 30 minutes, 30 to less than 60 minutes, 60 to less than 90 minutes, and 90 minutes to 48 hours. Age at enrollment in the study was categorized as 65 years or younger, 66 to 79 years, and 80 years or older. Sex and age groups’ time differences were assessed visually with boxplots and with Wilcoxon rank sum and Kruskal-Wallis nonparametric tests. Recall period for subject interviews was calculated as the number of days between the date of symptom onset and the date of subject interview. Recall period and differences in the time of symptom onset were graphically assessed using a scatterplot and Locally Weighted Scatterplot Smoother and analyzed with Spearman rank correlations ($r_s$). Multivariable median regression modeling was used to assess the associations of sex, age groups, and length of recall period (after log-transformation) with the time of symptom onset, adjusting for randomized group assignment and site. All analyses were performed in SAS v 9.3 (SAS Institute, Cary, North Carolina). A 2-sided $P > .05$ was considered statistically significant.

RESULTS

The mean (SD) age at enrollment of the 251 patients at enrollment was 66.8 (11.8) years. About a third (35%) were women. Fifteen (6%) patients had missing dates for interviews, so their recall period could not be calculated. Of the 236 who had dates for interviews, the median number of days between the date of symptoms onset and the interview was 29.5 days (mean [SD], 83.9 [129.4] days). Table 1 gives the characteristics of the patient sample.

Of the 251 subjects with complete data, the median difference between the 2 data sources for the time of symptom onset was 45.0 minutes (mean [SD], 303.1 [530.3] minutes) (see Table 2). There was no significant difference in the time of symptom onset between men and women ($P = .72$) for the 2 sources. The median difference between the 2 data sources in the time of symptom onset by age groups was 40.0 minutes for 65 years or younger, 40.0 minutes for 66 to 79 years, and 132.5 minutes for 80 years or older, although these did not differ statistically ($P = .188$).

$^a$For patients with differences of 48 hours or less of time from symptom onset between medical record and interview.

Greater differences in the time of symptom onset between the MR and the interview were associated with longer recall periods (see the Figure). Specifically, there was a significant correlation between differences in the time from symptom onset and recall ($r_s = 0.148$, $P = .023$). Using multivariable median regression (see Table 3), there were no significant associations with differences between the 2 data sources in the time of symptom onset, except for log-transformed length of recall period ($P = .023$). Longer recall periods were significantly associated with greater differences in the time of symptom onset between the MR and interviews, adjusting for other model covariates ($b = 13.2; 95\%$ confidence interval, 1.9-24.6). For example, interviews conducted 3 days after the event were associated with an 18-minute difference; interviews done 7 days afterward were associated with a 27-minute difference. If the recall period was greater than approximately 9 days, the difference between the 2 data sources exceeded 30 minutes.

DISCUSSION

We found significant discrepancies between the MR and patient interview in time of symptom onset, but with no definitive indication of which was more accurate. Notably, a longer recall period was associated with a greater difference in the 2 sources of information. On the basis of these findings, nearly half (49%) of the patients in this study had more than a 1-hour difference between the 2 data sources. As determined in this study, a median difference of 45 minutes between the 2 data sources is clinically meaningful given that past studies have shown that for every 30 minutes of prehospital delay, there is a 7.5% increase in mortality.\textsuperscript{14}

We also found that in this study, the percentage of missing symptom onset data was much lower in the MR as compared with subject interviews done after the index event (3% vs 15%, respectively). In addition, this percentage of missing data in the MR in this study is markedly lower than that reported in previous studies (3% in the current study vs 14%-40%).\textsuperscript{3-7} It is possible that the ED clinicians were educated in advance of the PROMOTION study about the importance of documenting the time of symptom onset. However, the percentage of missing data from subject interviews in this study was about the same as reported in past studies (15% in current study vs 12%-13%).\textsuperscript{5,6} One explanation for a higher percentage of missing data from subject interviews is that the median length of time between the index event and the subject interview was about a month (29.5 days). Although the interviews were conducted by trained researchers, the length of time between the actual event and the interview probably influenced patients’ ability to remember the time of symptom onset. Thus, we recommend that data from subject interviews not be used to collect the time of symptom onset if the interviews are not conducted within 72 hours of the hospital admission.

No differences by age or sex were noted related to discrepancies between the MR and the subject interview. One explanation for a lack of significant differences between the 2 data sources based on sex and age is that assessment techniques may have improved in patient groups that are more likely to have atypical symptoms (women and the elderly).
STRENGTHS AND LIMITATIONS

One strength of the study was that it is a multicenter international study that reported a low percentage of missing or incomplete data from the MR as compared with past studies in the literature. However, one limitation of this study is that the time of symptom onset from both data sources was from subject report provided retrospectively after the symptoms had occurred. Thus, no direct observations were done to determine the exact time of symptom onset in real time.

IMPLICATIONS FOR CLINICAL PRACTICE

Clinicians in acute and critical care settings face several challenges with obtaining an accurate time of symptom onset for patients presenting with suspected ACS and must do so within a time sensitive context. Clinicians are first charged with ensuring that symptoms of ischemia are assessed broadly, beyond chest pain as a single symptom, to avoid missing a potential ACS diagnosis. Second, clinicians may encounter patients who have difficulty articulating their symptom experience based on the questions asked. For example, some patients may have symptoms that evolve gradually, making it difficult for them to pinpoint the exact time of onset. Other patients may have difficulty quantifying vague or atypical symptoms. To overcome these challenges, there is need for a standardized evidence-based assessment procedure for patients with suspected ACS. Use of a standardized procedure would decrease the variability in clinical practice and provide evidence-based care for all patients with suspected ACS. For example, DeVon and colleagues have developed a 13-item ACS symptom checklist to be used for both clinical assessment and research. The instrument has established reliability and validity for use as a rapid triage assessment tool and is suitable for integration in an electronic health record (EHR).

Furthermore, incorporation of a standardized assessment procedure in the EHR has other potential advantages, such as improving completeness of documentation of symptoms, including the time of symptom onset. Clinicians in acute and critical care settings have an opportunity and an obligation to be champions in designing and using efficient assessment data collection processes. Input by clinicians can include which data elements should be entered as structured data (eg, quantifiable data such as systolic blood pressure or pain intensity level), discrete data in predefined categories (eg, presence or absence of certain ACS symptoms), or as textual data (eg, narrative data entered as free text). Clinicians can also provide input into clinical decision support tools, such as “Smart” computer assisted data entry options, which prompt clinicians to enter discrete data or double-check data entered (eg, the EHR can precalculate the time of symptom onset to hospital arrival). Options for rephrasing assessment questions could be used if a patient has difficulty answering a specific question related to symptoms. Furthermore, “real-time” flags can be provided alerting the clinician that data are missing, thus providing an opportunity to increase completeness of assessment and documentation during the initial patient encounter.

CONCLUSION

The findings from this study provide important information on assessing the time of cardiac symptom onset. The 2 data sources (MR vs subject interviews done after the acute event) are
clearly not interchangeable, especially if the interviews are done more than 3 days after the index event. These findings indicate that documentation of symptom onset time in the MR has improved compared with previous studies. However, clinicians in acute and critical care settings should remain vigilant about accurate assessment and documentation of cardiac symptoms, especially in those patients with less discrete symptom onset.
